Glenn C. Hamilton (Editions 5 and 6)
We wish to dedicate this 7th edition to Peter Rosen, MD, the founder of this textbook and its Editor-in-Chief through the first four editions. Thirty-one years ago, in 1978, Peter came to the belief that an emergency medicine textbook should be written by emergency physicians, and 5 years later, in 1983, he was the first to carry out that mission when the inaugural edition of this textbook was published. While this eponymous work is significant, Peter is more widely acknowledged as one of the true fathers of academic emergency medicine. He continues to leave his imprimatur on numerous programs and innumerable medical students, residents, and faculty members throughout the country and indeed the world. Many of these individuals, like ourselves, have tried to emulate his unbending leadership, his passion for teaching, and his reverence for emergency medicine and the patients we have the great privilege to serve.

This textbook represents just one of many exemplary accomplishments of one extraordinary man. We are indebted to Peter for his vision and his wisdom. We are unspeakably grateful for the honor of continuing this work, ever humbled by the responsibility of carrying his legacy forward, and beholden to him for helping craft our specialty into what it is today.

Ron M. Walls
How this Medical Textbook Should Be Viewed by the Practicing Clinician and the Judicial System

The editors and authors of this textbook strongly believe that the complex practice of medicine, the vagaries of human diseases, the unpredictability of pathologic conditions, and the functions, dysfunctions, and responses of the human body cannot be defined, explained, or rigidly categorized by any written document. Therefore, it is neither the purpose nor intent of our textbook to serve as an authoritative source on any medical condition, treatment plan, or clinical intervention, nor should our textbook be used to rigorously define a standard of care that should be practiced by all clinicians.

Our written word provides the physician with a literature-referenced database, and a reasonable clinical guide, which is combined with practical suggestions from individual experienced practitioners. We offer a general reference source and clinical roadmap on a variety of conditions and procedures that may confront clinicians who are experienced in emergency medicine practice. This text cannot replace physician judgment; cannot describe every possible aberration, nuance, clinical scenario, or presentation; and cannot define rigid standards for clinical actions or procedures. Every medical encounter must be individualized, and every patient must be approached on a case-by-case basis. No complex medical interaction can possibly be reduced to the written word. The treatments, procedures, and medical conditions described in our textbook do not constitute the total expertise or knowledge base expected to be possessed by all clinicians. Finally, many of the described complications and adverse outcomes associated with implementing or withholding complex medical and surgical interventions may occur, even when every aspect of the intervention has been standard or performed correctly.

The editors and authors of Rosen's Emergency Medicine: Concepts and Clinical Practice, 7th Edition

Contributors

Cynthia K. Aaron, MD
Professor, Emergency Medicine and Pediatrics, Wayne State University School of Medicine; Program Director, Medical Toxicology; Education Director, Regional Poison Center; Associate Medical Director, Regional Poison Center, Children’s Hospital of Michigan, Part of the Detroit Medical Center, Detroit, Michigan

Jean T. Abbott, MD, MH
Professor Emeritus, Emergency Medicine; Faculty, Center for Bioethics and Humanities, University of Colorado School of Medicine; Attending Physician, Anschutz Medical Center, Aurora, Colorado

Riyad B. Abu-Laban, MD, MHSc, FRCPC
Associate Professor and Co-Research Director, Department of Emergency Medicine, University of British Columbia; Attending Physician, Department of Emergency Medicine, Vancouver General Hospital, Vancouver, British Columbia, Canada

Bruce D. Adams, MD, FACEP, Colonel, Medical Corps, U.S. Army
Clinical Professor of Emergency Medicine, Medical College of Georgia, Augusta, Georgia; Chief, Department of Clinical Investigations and Chief, Department of Emergency Medicine, William Beaumont Army Medical Center, El Paso, Texas

James G. Adams, MD
Professor and Chair, Department of Emergency Medicine, Feinberg School of Medicine, Northwestern University; Chair, Department of Emergency Medicine, Northwestern Memorial Hospital, Chicago, Illinois

Stephen L. Adams, MD
Professor and Chief, Division of Sports Medicine, Department of Medicine, Northwestern University, Feinberg School of Medicine; Medical Director, Emergency Preparedness/Disaster Services, Northwestern Memorial Hospital; Team Physician, Chicago Cubs National League Baseball Club, Chicago, Illinois

Terry A. Adirim, MD, MPH
Associate Chief Medical Officer, Office of Health Affairs, U.S. Department of Homeland Security, Washington, DC; Attending Physician, Pediatric Emergency Department, Shady Grove Adventist Hospital, Rockville, Maryland

Kumar Alagappan, MD
Associate Professor, Albert Einstein College of Medicine, Bronx, New York; Associate Chairman, Emergency Medicine, Long Island Jewish Medical Center, New Hyde Park, New York

James T. Amsterdam, DMD, MD, MMM
Adjunct Professor of Emergency Medicine, Drexel University College of Medicine, Philadelphia, Pennsylvania; Professor of Clinical Emergency Medicine, Pennsylvania State University College of Medicine, Hershey, Pennsylvania; Chair and Service Line Director, Department of Emergency Medicine, York Hospital/WellSpan Health, York, Pennsylvania

Christine Anderegg, MD
Attending Physician, Department of Emergency Medicine, Davis Hospital and Medical Center, Layton, Utah

Megan L. Anderson, MD
Department of Emergency Medicine, University of Michigan, Ann Arbor, Michigan

Deirdre Anglin, MD
Professor of Emergency Medicine, Keck School of Medicine, University of Southern California; Attending Physician, Los Angeles County and University of Southern California Medical Center, Los Angeles, California

Felix Ankel, MD
Associate Professor of Emergency Medicine, University of Minnesota, Minneapolis, Minnesota; Residency Director and Assistant Department Head, Emergency Medicine, Regions Hospital, St. Paul, Minnesota

Sanjay Arora, MD
Associate Professor of Clinical Emergency Medicine, University of Southern California, Keck School of Medicine, Los Angeles County Hospital, Los Angeles, California

Tom P. Aufderheide, MD, FACEP, FAHA
Professor of Emergency Medicine and Associate Chair of Research Affairs, Department of Emergency Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin

Kevin M. Ban, MD
Assistant Clinical Professor, Harvard Medical School; Attending Physician, Beth Israel Deaconess Medical Center, Boston, Massachusetts
Emily Baran, MD
Assistant Professor, Department of Emergency Medicine, Feinberg School of Medicine, Northwestern University; Attending Physician, Northwestern Memorial Hospital, Chicago, Illinois

Christina E. Hantsch Bardsley, MD, FACEP, FACMT
Associate Professor, Department of Surgery, Division of Emergency Medicine, Stritch School of Medicine, Loyola University Chicago, Chicago, Illinois; Attending Physician, Emergency Medicine and Medical Toxicology, Loyola University Medical Center, Maywood, Illinois

Adam Z. Barkin, MD, MPH
Clinical Instructor, Department of Surgery; Clinical Instructor, Department of Pediatrics, University of Colorado School of Medicine; Attending Physician, Rose Medical Center, Denver, Colorado

Andrew R. Barnosky, DO, MPH
Associate Professor, Emergency Medicine, University of Michigan Medical School; Associate Professor and Attending Physician, University of Michigan Health System, Department of Emergency Medicine, Ann Arbor, Michigan

William G. Barsan, MD
Professor and Chair, Department of Emergency Medicine, University of Michigan, Ann Arbor, Michigan

Bruce M. Becker, MD, MPH
Professor, Emergency Medicine and Community Health, Warren Alpert School of Medicine, Brown University; Attending Physician, Department of Emergency Medicine, Rhode Island Hospital and Hasbro Children’s Hospital, Providence, Rhode Island

Rimon N. Bengiamin, MD
Clinical Instructor, University of California San Francisco—Fresno, Fresno, California

Marc D. Berg, MD
Associate Professor of Clinical Pediatrics, University of Arizona, College of Medicine, Tucson, Arizona

Robert A. Berg, MD
Professor of Anesthesiology and Critical Care, University of Pennsylvania School of Medicine; Division Chief, Critical Care Medicine, Children’s Hospital of Philadelphia, Philadelphia, Pennsylvania

Carol D. Berkowitz, MD
Professor of Clinical Pediatrics, David Geffen School of Medicine at the University of California at Los Angeles, Los Angeles, California; Executive Vice-Chair, Department of Pediatrics, Harbor-University of California at Los Angeles Medical Center, Torrance, California

Edward Bernstein, MD
Professor and Vice-Chair for Academic Affairs, Department of Emergency Medicine, Boston University School of Medicine, Boston, Massachusetts

Judith Bernstein, PhD, RNC
Associate Professor, Department of Emergency Medicine, Boston University School of Medicine; Associate Professor, Department of Maternal and Child Health, Boston University School of Public Health, Boston, Massachusetts

Howard A. Bessen, MD
Professor of Medicine, David Geffen School of Medicine at University of California at Los Angeles; Senior Faculty Member, Department of Emergency Medicine, Harbor-University of California at Los Angeles Medical Center, Torrance, California

Kriti Bhatia, MD
Clinical Instructor, Harvard Medical School; Attending Physician, Department of Emergency Medicine, Brigham and Women’s Hospital; Associate Residency Director, Harvard Affiliated Emergency Medicine Residency, Brigham and Women’s Hospital, Boston, Massachusetts

Elisabeth F. Bilden, MD
Associate Medical Director, Hennepin County Medical Center, Minneapolis, Minnesota; Attending Physician, St. Mary’s Duluth Clinic, Duluth, Minnesota

Diane M. Birnbaumer, MD
Professor of Clinical Medicine, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Associate Residency Program Director, Department of Emergency Medicine, Harbor-University of California at Los Angeles Medical Center, Torrance, California

Michelle H. Biros, MD, MS
Professor, Emergency Medicine, University of Minnesota Medical School and Hennepin County Medical Center; Vice Chair of Research-Emergency Medicine, University of Minnesota Medical School; Associate Research Director, Hennepin County Medical Center, Minneapolis, Minnesota

Robert A. Bitterman, MD, JD
President, Bitterman Health Law Consulting Group, Inc., Harbor Springs, Michigan; President, Emergency Physicians Insurance Company (EPIC), Auburn, California

Thomas H. Blackwell, MD
Clinical Associate Professor, School of Medicine, University of North Carolina—Chapel Hill, Chapel Hill, North Carolina; Medical Director, Center for Prehospital Medicine, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina

Frederick C. Blum, MD, FACEP, FAAP, FIFEM
Associate Professor of Emergency Medicine and Pediatrics, West Virginia University School of Medicine, Morgantown, West Virginia

Ira J. Blumen, MD
Professor, Section of Emergency Medicine, Department of Medicine, University of Chicago; Program/Medical Director, University of Chicago Aeromedical Network (UCAN), University of Chicago Medical Center, Chicago, Illinois

Jennifer M. Bocock, MD, FACEP
Attending Physician, Department of Emergency Medicine, Kettering Medical Center, Kettering, Ohio

Edward B. Bolgiano, MD, FACP, FACEP
Assistant Professor, Departments of Medicine and Surgery, University of Maryland School of Medicine; Chief, Department of Emergency Medicine, Bon Secours Hospital, Baltimore, Maryland
Laura J. Bontempo, MD  
Assistant Professor and Residency Program Director, Section of Emergency Medicine, Department of Surgery, Yale University School of Medicine, New Haven, Connecticut

William J. Brady, MD  
Professor of Emergency Medicine and Medicine, Vice-Chair, Department of Emergency Medicine, University of Virginia School of Medicine; Medical Director, Mondial Assistance USA and Canada, Charlottesville, Virginia

Sabina Braithwaite, MD  
Associate Professor of Emergency Medicine, University of Virginia, Charlottesville, Virginia

Calvin A. Brown III, MD  
Instructor in Medicine (Emergency Medicine), Harvard Medical School; Attending Physician, Brigham and Women’s Hospital, Boston, Massachusetts

James E. Brown, MD  
Program Director and Vice-Chair, Department of Emergency Medicine, Wright State University, Dayton, Ohio

Douglas D. Brunette, MD, MPH  
Associate Professor, University of Minnesota Medical School, Department of Emergency Medicine; Assistant Chief, Hennepin County Medical Center, Department of Emergency Medicine, Minneapolis, Minnesota

Gavin R. Budhram, MD, RDMS  
Assistant Professor of Emergency Medicine, Tufts University School of Medicine, Western Campus; Staff Physician, Director of Emergency Ultrasound, Baystate Medical Center, Springfield, Massachusetts

E. Bradshaw Bunney, MD  
Associate Professor, Residency Director, University of Illinois at Chicago; Attending Physician, Department of Emergency Medicine, University of Illinois Hospital, Chicago, Illinois

David Burbulys, MD  
Associate Professor of Clinical Medicine, David Geffen School of Medicine at University of California at Los Angeles; Director, Residency Program, Department of Emergency Medicine, Harbor-UCLA Medical Center, Torrance, California

Michael J. Burns, MD, FACEP, FACP  
Clinical Professor, Departments of Emergency Medicine and Medicine, Division of Infectious Diseases, University of California, Irvine School of Medicine, Irvine, California; Attending Physician, Emergency Medicine and Infectious Diseases, University of California, Irvine Medical Center, Orange, California

Richard L. Byyny, MD, MSc  
Assistant Professor, Division of Surgery, University of Colorado, School of Medicine, Aurora, Colorado; Associate Director of Research, Denver Health Medical Center Residency in Emergency Medicine, Denver Health Medical Center, Denver, Colorado

John D. Cahill, MD  
Assistant Professor of Clinical Medicine, Columbia College of Physicians and Surgeons, New York, New York; Adjunct Assistant Professor of Emergency Medicine, Warren Alpert School of Medicine, Brown University, Providence, Rhode Island; Visiting Senior Lecturer in International Health and Tropical Medicine, The Royal College of Surgeons, Dublin, Ireland; Senior Attending Physician in Emergency Medicine and Infectious Diseases, Global Health Fellowship Director, St. Luke’s Roosevelt Hospital Center, New York, New York

Kirsten K. Calder, MD, FACEP  
Staff Physician, Department of Emergency Medicine, Los Alamitos Medical Center, Los Alamitos, California

Richard M. Cantor, MD, FAAP, FACEP  
Associate Professor and Director, Pediatric Emergency Medicine, Department of Emergency Medicine; Medical Director, Central New York Regional Poison Control Center, State University of New York, Upstate Medical University College of Medicine, Syracuse, New York

Stuart M. Caplen, MD  
Lean Project Coordinator, Emergency Department, Montefiore North Division, Bronx, New York; Attending Physician, Emergency Department, Metropolitan Hospital Center, New York, New York

Andrea Carlson, MD  
Attending Physician, Emergency Medicine, Director, Medical Toxicology, Advocate Christ Hospital, Oak Lawn, Illinois

Theodore C. Chan, MD  
Professor of Clinical Medicine, University of California at San Diego; Medical Director, Emergency Department, University of California, San Diego Medical Center, San Diego, California

Lei Chen, MD  
Assistant Professor, Section of Pediatric Emergency Medicine, Department of Pediatrics, Yale University School of Medicine; Attending Physician, Yale-New Haven Children’s Hospital, New Haven, Connecticut

Stephen B. Choi, MD, FRCP  
Associate Residency Director, Department of Emergency Medicine, University of Ottawa; Assistant Professor, University of Ottawa; Co-Editor-in Chief, Open Medicine, Ottawa, Ontario, Canada

Richard F. Clark, MD  
Professor of Medicine, University of California at San Diego; Director, Division of Medical Toxicology, University of California at San Diego Medical Center, San Diego, California

Philip A. Clement, MD, FACEP  
Clinical Assistant Professor, Department of Emergency Medicine, East Carolina University, Brody School of Medicine; Attending Physician, Pitt County Memorial Hospital, Greenville, North Carolina
Wendy C. Coates, MD
Professor of Medicine, Chair, Acute Care College, David Geffen School of Medicine, University of California at Los Angeles, Los Angeles, California; Director, Medical Education, Harbor-University of California at Los Angeles Medical Center, Department of Emergency Medicine, Huntington Beach, California

Robert E. Collier, MD
Assistant Professor of Emergency Medicine, University of Minnesota School of Medicine; Emergency Medicine Faculty, Hyperbaric Medicine Fellowship Director, Hennepin County Medical Center, Minneapolis, Minnesota

Jamie L. Collings, MD
Associate Professor, Department of Emergency Medicine, Northwestern University, Feinberg School of Medicine; Residency Director, Department of Emergency Medicine, Northwestern Memorial Hospital, Chicago, Illinois

Stephen A. Colucciello, MD, FACEP
Adjunct Professor of Emergency Medicine, University of North Carolina School of Medicine—Chapel Hill, Chapel Hill, North Carolina; Vice Chief Emergency Medicine, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina

Christopher B. Colwell, MD
Associate Professor, Department of Surgery, Division of Emergency Medicine, University of Colorado at Denver, School of Medicine; Associate Director, Department of Emergency Medicine, Denver Health Medical Center, Denver, Colorado

Edward E. Conway, Jr., MD, MS
Professor of Clinical Pediatrics, Albert Einstein College of Medicine, Bronx, New York; Chairman, Milton and Bernice Stern Department of Pediatrics, Chief of Pediatric Critical Care Medicine, Beth Israel Medical Center, New York, New York

Jeremy L. Cooke, MD
Assistant Professor, Department of Emergency Medicine, University of California at Davis; Assistant Professor of Emergency Medicine, University of California at Davis Medical Center, Sacramento, California

Mary Ann Cooper, MD
Professor (Retired), Departments of Bioengineering and Emergency Medicine, University of Illinois at Chicago, Chicago, Illinois

Randolph J. Cordle, MD
Adjunct Assistant Professor, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina; Medical Director, Division of Pediatric Emergency Medicine; Program Director, Pediatric Emergency Medicine Fellowship, Levine Children’s Hospital, Department of Emergency Medicine, Charlotte, North Carolina

Sandy A. Craig, MD
Adjunct Associate Professor, Department of Emergency Medicine, University of North Carolina School of Medicine, Chapel Hill, North Carolina; Faculty, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina

Hilarie Cranmer, MD, MPH
Assistant Professor, Harvard Medical School; Attending Emergency Medicine Director, Global Women’s Health Fellowship, Education Director, Harvard Humanitarian Initiative, Brigham and Women’s Hospital, Boston, Massachusetts

Todd J. Crocco, MD
Associate Professor and Chair, Department of Emergency Medicine, West Virginia University School of Medicine, Morgantown, West Virginia

Pat Croskerry, MD, PhD
Senior Research Scientist, Dalhousie University, Halifax, Nova Scotia, Canada; Attending Physician, Dartmouth General Hospital, Dartmouth, Nova Scotia, Canada

A. Adam Cwinn, MD, FRCP
Professor, Department of Emergency Medicine, The University of Ottawa; Head, Department of Emergency Medicine and Medical Director of Critical Care and Emergency Medicine, The Ottawa Hospital, Ottawa, Ontario, Canada

Rita K. Cydulka, MD, MS
Professor, Emergency Medicine, Case Western Reserve University School of Medicine, Cleveland, Ohio; Vice Chair, MetroHealth Medical Center, Shaker Heights, Ohio

Daniel F. Danzl, MD
Professor and Chair, Department of Emergency Medicine, University of Louisville School of Medicine, Louisville, Kentucky

Ana M. Davitt, MD
Attending Physician, Pennsylvania Hospital, University of Pennsylvania Health System, Philadelphia, Pennsylvania

Mohamud Daya, MD
Associate Professor, Department of Emergency Medicine, Oregon Health and Science University, Portland, Oregon

Kathleen A. Delaney, MD, MS
Professor, Division of Emergency Medicine, University of Texas, Southwestern Medical School; Vice Chair of Emergency Medicine, Parkland Memorial Hospital, Dallas, Texas

Theodore R. Delbridge, MD, MPH
Professor of Emergency Medicine, Brody School of Medicine at East Carolina University; Chief of Emergency Services, Department of Emergency Medicine, Pitt County Memorial Hospital, Greenville, North Carolina

Robert A. De Lorenzo, MD, MSM
Professor of Military and Emergency Medicine, Uniformed Services University of the Health Sciences, Bethesda, Maryland; Colonel Medical Corps, U.S. Army, Brooke Army Medical Center, Fort Sam Houston, Houston, Texas

Robert W. Derlet, MD
Professor Emeritus, Department of Emergency Medicine, University of California Davis School of Medicine, Sacramento, California

Shoma Desai, MD, BA
Assistant Professor of Clinical Emergency Medicine, University of Southern California; Quality Assurance Director, Los Angeles County and University of Southern California Medical Center, Los Angeles, California
Bram A. Dolcourt, MD
Assistant Professor, Wayne State University School of Medicine; Medical Toxicologist, Children’s Hospital of Michigan Regional Poison Control Center, Detroit, Michigan

Evelyn H. Duvivier, MD, MPH
Attending Physician, Pennsylvania Hospital, Philadelphia, Pennsylvania

Joshua S. Easter, MD
Clinical Fellow, Harvard Medical School; Clinical Pediatric Emergency Medicine Fellow, Department of Emergency Medicine, Children’s Hospital of Boston, Boston, Massachusetts

Marc Eckstein, MD, MPH
Associate Professor of Emergency Medicine, Keck School of Medicine of the University of Southern California; Medical Director, Los Angeles Fire Department; Director of Prehospital Care—Los Angeles County/University of Southern California Medical Center, Los Angeles, California

Mary Eisenhauer, MD, FRCPC
Associate Professor of Medicine, Schulich School of Medicine and Dentistry, University of Western Ontario; Consultant, London Health Sciences Centre, London, Ontario, Canada

Matt Emery, MD, FACEP
Assistant Professor of Emergency Medicine, Michigan State University-CHM, East Lansing, Michigan; Educational Assistant, MSU-MERC Program in Emergency Medicine, Spectrum Health, Butterworth Campus, Grand Rapids, Michigan

Jay L. Falk, MD, FACEP, FCCM
Professor of Medicine and Emergency Medicine, University of Central Florida, College of Medicine; Clinical Professor, Clinical Sciences, Florida State University, College of Medicine; Academic Chairman, Department of Emergency Medicine, Orlando Regional Medical Center; Vice President of Medical Education, Orlando Health, Orlando, Florida

Sing-Yi Feng, MD
Assistant Professor, Department of Pediatrics, Division of Emergency Medicine, University of Texas Southwestern Medical Center at Dallas; Medical Toxicologist, North Texas Poison Center, Parkland Memorial Hospital, Dallas, Texas

Madonna Fernández-Frackelton, MD
Associate Professor of Medicine, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Associate Residency Director, Harbor-University of California at Los Angeles Medical Center, Torrance, California

James F. Fiechtl, MD
Assistant Professor, Department of Emergency Medicine, Vanderbilt University Medical Center, Nashville, Tennessee

John T. Finnell, II, MD, MSc
Associate Professor of Emergency Medicine, Indiana University; Research Scientist, Regenstrief Institute, Indianapolis, Indiana

Robert W. Fitch, MD
Assistant Professor, Department of Emergency Medicine; Assistant Professor, Department of Orthopedics and Rehabilitation, Vanderbilt University Medical Center, Nashville, Tennessee

Mark Foran, MD
Clinical Fellow in Emergency Medicine, Harvard Medical School; Resident Physician, Harvard Affiliated Emergency Medicine Residency, Brigham and Women’s Hospital, Massachusetts General Hospital, Boston, Massachusetts

E. John Gallagher, MD
Professor and University Chair, Department of Emergency Medicine, Albert Einstein College of Medicine of Yeshiva University; Chief of Service, Emergency Medicine, Montefiore Medical Center, Bronx, New York

Boris Garber, DO
Assistant Professor, Case Western Reserve University School of Medicine; Attending Physician, MetroHealth Medical Center, Cleveland, Ohio

Marianne Gausche-Hill, MD, FACEP, FAAP
Professor of Clinical Medicine, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Director of EMS and Pediatric Emergency Fellowships, Department of Emergency Medicine, Harbor-University of California at Los Angeles Medical Center, Torrance, California

Mark E. Gebhart, MD, FAAEM
Assistant Professor of Emergency Medicine, Wright State University School of Medicine; Staff Physician, Emergency and Trauma Center, Good Samaritan Hospital, Dayton, Ohio

Joel M. Geiderman, MD, FACEP
Professor of Emergency Medicine, Cedars-Sinai Medical Center; Professor of Medicine, David Geffen School of Medicine at University of California at Los Angeles; Co-Chairman, Department of Emergency Medicine, Cedars-Sinai Medical Center, Los Angeles, California

Michael A. Gibbs, MD, FACEP
Professor of Emergency Medicine, Tufts University School of Medicine, Boston, Massachusetts; Chief, Department of Emergency Medicine, Maine Medical Center, Portland, Maine

Casey M. Glass, MD
Assistant Professor, Department of Emergency Medicine, Wake Forest University Health Sciences; Director of Community Emergency Ultrasound Programs, Wake Forest University Health Sciences Department of Emergency Medicine; Assistant Medical Director, Emergency Medicine, Wilkes Regional Medical Center, North Wilkesboro, North Carolina; North Carolinas Baptist Medical Center, Winston-Salem, North Carolina

Richard Goldberg, MD
Clinical Professor of Emergency Medicine, Department of Emergency Medicine, Los Angeles County and University of Southern California Medical Center, Los Angeles, California; Staff Physician, Providence Saint Joseph Medical Center, Burbank, California
Contributors

John E. Gough, MD
Professor, Department of Emergency Medicine, East Carolina University, Brody School of Medicine; Attending Physician, Pitt County Memorial Hospital, Greenville, North Carolina

Louis Graff IV, MD, FACP, FACEP
Professor of Emergency Medicine, Professor of Clinical Medicine, University of Connecticut School of Medicine, Farmington, Connecticut; Medical Director of Quality, Associate Director of Emergency Medicine, Hospital of Central Connecticut, New Britain, Connecticut

Richard O. Gray, MD
Assistant Professor of Emergency Medicine, University of Minnesota Medical School; Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, Minnesota

Eric Gross, MD
Assistant Professor, Department of Emergency Medicine, University of Minnesota Medical School; Assistant Residency Director, Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, Minnesota

John A. Guisto, MD
Associate Professor, Department of Emergency Medicine, University of Arizona College of Medicine; Medical Director, Emergency Department, University Medical Center, Tucson, Arizona

David A. Guss, MD
Professor and Chair, University of California at San Diego, Department of Emergency Medicine, University of California San Diego School of Medicine, San Diego, California

Leon Gussow, MD
Lecturer, Department of Emergency Medicine, University of Illinois; Instructor, Department of Emergency Medicine, Rush Medical College; Attending Physician, John H. Stroger, Jr. Hospital of Cook County, Chicago, Illinois

Rania Habal, MD
Assistant Clinical Professor, Emergency Medicine, New York Medical College, Valhalla, New York; Attending Physician, Emergency Medicine, Metropolitan Hospital Center, New York, New York

Tenagne Haile-Mariam, MD
Assistant Professor, Department of Emergency Medicine, George Washington University Medical Center, Washington, DC

Glenn C. Hamilton, MD
Professor and Chair, Department of Emergency Medicine, Wright State University, Dayton, Ohio

Professor, Department of Emergency Medicine, Medical College of Wisconsin; Director, Emergency Medicine, Froedtert Hospital, Milwaukee, Wisconsin

Richard A. Harrigan, MD
Professor of Emergency Medicine, Temple University School of Medicine, Temple University, Philadelphia, Pennsylvania

William G. Heegaard, MD, MPH
Associate Professor, University of Minnesota Medical School, Department of Emergency Medicine; Assistant Chief, Hennepin County Medical Center, Department of Emergency Medicine, Minneapolis, Minnesota

Jag S. Heer, MD, FAAEM
Assistant Clinical Professor, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Attending Faculty Department of Emergency Medicine, Kern Medical Center, Bakersfield, California

Katherine L. Heilpern, MD
Professor and Chair, Department of Emergency Medicine, Emory University School of Medicine, Atlanta, Georgia

Robin R. Hemphill, MD, MPH
Associate Professor, Department of Emergency Medicine, Emory University School of Medicine; Director of Patient Safety and Quality, Emory University Hospital, Atlanta, Georgia

Sean O. Henderson, MD
Associate Professor of Emergency and Preventive Medicine, Keck School of Medicine of the University of California; Vice Chair, Department of Emergency Medicine LAC and USC Medical Center, Los Angeles, California

Robert G. Hendrickson, MD
Associate Professor, Department of Emergency Medicine, Oregon Health and Science University; Associate Medical Director, Medical Toxicologist, Oregon Poison Center; Associate Fellowship Director, Program in Medical Toxicology, Oregon Health and Science University, Portland, Oregon

Philip L. Henneman, MD
Professor of Emergency Medicine, Tufts University School of Medicine, Boston, Massachusetts; Attending Physician, Department of Emergency Medicine, Baystate Medical Center, Springfield, Massachusetts

H. Gene Hern, Jr., MD
Assistant Clinical Professor of Emergency Medicine, University of California at San Francisco, San Francisco, California; Residency Director, Alameda County Medical Center, Oakland, California

Kendall Ho, MD, FRCPC
Associate Professor, Department of Emergency Medicine, Faculty of Medicine, University of British Columbia; Attending Staff, Department of Emergency Medicine, Vancouver General Hospital, Vancouver, British Columbia, Canada

Robert S. Hockberger, MD
Professor of Medicine, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Chair, Department of Emergency Medicine, Harbor-University of California at Los Angeles Medical Center, Torrance, California

Robert S. Hoffman, MD
Associate Professor of Emergency Medicine and Medicine (Clinical Pharmacology), New York University School of Medicine; Attending Physician, Bellevue Hospital Center, New York, New York
Benjamin Honigman, MD  
Professor of Surgery, University of Colorado Denver, School of Medicine; Head, Division of Emergency Medicine, Department of Emergency Medicine, University of Colorado Hospital, Aurora, Colorado

Timothy Horeczko, MD  
Clinical Instructor of Medicine, David Geffen School of Medicine at the University of California, Los Angeles, Los Angeles, California; Pediatric Emergency Medicine Fellow, Department of Emergency Medicine, Harbor-University of California at Los Angeles Medical Center, Los Angeles County Harbor-University of California at Los Angeles Medical Center, Torrance, California

Mark A. Hostetler, MD, MPH  
Clinical Professor, Departments of Pediatrics and Emergency Medicine, The University of Arizona College of Medicine; Attending Physician, Phoenix Children’s Hospital, Phoenix, Arizona

Debra E. Houry, MD, MPH  
Assistant Professor, Department of Emergency Medicine, Emory School of Medicine; Assistant Professor, Department of Environmental and Occupational Health and Department of Behavioral Sciences and Health Education, Rollins School of Public Health; Director, Center for Injury Control, Emory University, Atlanta; Attending Emergency Physician, Emory University Hospital, Atlanta, Georgia

J. Stephen Huff, MD  
Associate Professor of Emergency Medicine and Neurology, Department of Emergency Medicine, University of Virginia Health System, Charlottesville, Virginia

Oliver Hung, MD  
Assistant Clinical Professor of Emergency Medicine, Mt. Sinai School of Medicine, New York, New York; Attending Physician, Department of Emergency Medicine, Morristown Memorial Hospital, Morristown, New Jersey

H. Range Hutson, MD  
Assistant Professor, Department of Emergency Medicine, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts

Alson S. Inaba, MD, FAAP  
Associate Professor of Pediatrics, University of Hawaii, John A. Burns School of Medicine; Director and Attending Physician, Pediatric Emergency Medicine Center, Kapi‘olani Medical Center for Women and Children, Honolulu, Hawaii

Jennifer L. Isenhour, MD  
Adjunct Assistant Professor, Department of Emergency Medicine, University of North Carolina—Chapel Hill, Chapel Hill, North Carolina; Associate Program Director, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina

Kenneth V. Iserson, MD, MBA, FACEP  
Professor Emeritus, Department of Emergency Medicine, University of Arizona College of Medicine, Tucson, Arizona

Kenneth Jackimczyk, MD, FACEP  
Attending Physician, Maricopa Medical Center, Phoenix, Arizona

Andy Jagoda, MD, FACEP  
Professor and Chair, Mt. Sinai School of Medicine; Medical Director, Mt. Sinai Medical Center, New York, New York

Thea L. James, MD  
Assistant Professor of Emergency Medicine, Department of Emergency Medicine, Boston University School of Medicine, Boston Medical Center, Boston, Massachusetts

Timothy G. Janz, MD  
Professor, Department of Emergency Medicine, Department of Internal Medicine, Boonshoft School of Medicine, Wright State University, Dayton, Ohio

Alan Jones, MD  
Adjunct Assistant Professor of Emergency Medicine, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina; Director, Emergency Medicine Critical Care Services; Assistant Director, Emergency Medicine Research, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina

James B. Jones, PharmD, MD  
Staff Physician, Mercy Hospital, Scranton, Pennsylvania

Jonathan S. Jones, MD  
Assistant Professor and Assistant Program Director, Department of Emergency Medicine, University of Mississippi Medical Center, Jackson, Mississippi

Nicholas J. Jouriles, MD  
Professor, Emergency Medicine, Northeastern Ohio Universities College of Medicine and Pharmacy, Rootstown, Ohio; Emergency Medicine Resident Care Faculty, Akron General Medical Center, Akron, Ohio

Amy H. Kaji, MD, PhD  
Assistant Clinical Professor of Emergency Medicine, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Assistant Clinical Professor of Emergency Medicine, Medical Director, Disaster Resource Center, Harbor-University of California at Los Angeles Medical Center, Torrance, California

Norman Kalbfleisch, MD  
Associate Professor, Oregon Health and Science University, Portland, Oregon

Louise Kao, MD  
Director, Medical Toxicology Fellowship Program; Assistant Professor of Clinical Emergency Medicine, Indiana University School of Medicine; Methodist Hospital/Clarian Health Partners, Indianapolis, Indiana

Dan Katz, MD, DTMH  
Assistant Clinical Professor of Medicine, David Geffen School of Medicine at University of California at Los Angeles; Medical Director of Academic Affairs, Department of Emergency Medicine, Cedars-Sinai Medical Center, Los Angeles, California

Matthew T. Keadey, MD, FACEP  
Assistant Professor, Emory University School of Medicine; Chief of Service, Department of Emergency Medicine, Emory University Hospital, Atlanta, Georgia
Eugene E. Kercher, MD, FACEP, FAPA
Chief Medical Officer, Director of Graduate Medical Education, Kern Medical Center, Bakersfield, California; Associate Clinical Professor of Medicine, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California

Kianusch Kiai, MD, MS
Clinical Associate Professor of Anesthesiology, Department of Anesthesiology, David Geffen School of Medicine at University of California at Los Angeles; Attending Physician, University of California at Los Angeles Ronald Reagan Medical Center, Los Angeles, California

Kelly E. King, MD
Medical Director, Casualty Care Research Center, Assistant Professor of Military and Emergency Medicine, Uniformed Services University of the Health Sciences, Bethesda, Maryland

Susan Kirelik, MD
Medical Director, Pediatric Emergency Services; Chair, Department of Pediatrics, Sky Ridge Medical Center, Lone Tree, Colorado

Eileen J. Klein, MD, MPH
Associate Professor, Pediatrics, University of Washington; Attending Physician, Seattle Children’s Hospital, Seattle, Washington

Jeffrey A. Kline, MD
Adjunct Professor of Emergency Medicine, University of North Carolina at Chapel Hill, Charlotte, North Carolina; Professor of Emergency Medicine, University of North Carolina—Chapel Hill; Director of Research, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina

Andrew L. Knaut, MD, PhD
Attending Physician, Emergency Physicians at Porter Hospitals, Denver, Colorado

Kristi L. Koenig, MD, FACEP
Professor of Emergency Medicine, Co-Director, EMS and Disaster Medical Sciences Fellowship, University of California at Irvine, School of Medicine; Director of Public Preparedness, University of California at Irvine, Orange, California

Amy V. Kontrick, MD
Assistant Professor of Emergency Medicine; Director, Undergraduate Medical Education, Northwestern University Feinberg School of Medicine, Chicago, Illinois

Dina Halpern Kornblau, MD, BA
Assistant Professor, Albert Einstein College of Medicine; Attending Physician and Director, Division of Pediatric Neurology, St. Barnabas Hospital, Bronx, New York

Joshua M. Kosowsky, MD
Assistant Professor, Harvard Medical School; Clinical Director, Department of Emergency Medicine, Brigham and Women’s Hospital, Boston, Massachusetts

Rashmi U. Kothari, MD
Associate Professor, Michigan State University/Kalamazoo Center for Medical Studies (MSU/KCMS); Director of Emergency Medicine Research, Borgess Research Institute, Borgess Hospital, Kalamazoo, Michigan

Baruch Krauss, MD, EdM
Associate Professor of Pediatrics, Department of Pediatrics, Harvard Medical School; Senior Associate Physician in Medicine, Division of Emergency Medicine, Children’s Hospital, Boston, Massachusetts

Ken Kulig, MD, FACMT, FAECT
Clinical Associate Professor, Emergency Medicine, University of Colorado; President Elect, Medical Staff, Porter Adventist Hospital, Denver, Colorado

Thomas Kwiatkowski, MD
Professor of Clinical Emergency Medicine, Albert Einstein College of Medicine, Bronx, New York; Medical Director, Patient Safety Institute; Faculty, Emergency Medicine, North Shore-Long Island Jewish Hospital Health System, Lake Success, New York

Frank W. Lavoie, MD
Vice President of Medical Affairs, Southern Maine Medical Center, Biddeford, Maine

Eric J. Lavonas, MD, FACEP, FACMT
Assistant Professor of Surgery (Emergency Medicine), University of Colorado, Denver, School of Medicine, Aurora, Colorado; Emergency Physician, Denver Health Medical Center; Associate Director, Rocky Mountain Poison and Drug Center, Denver Health Medical Center, Denver, Colorado

Christopher C. Lee, MD
Assistant Professor and Director of International Emergency Medicine Center, Stony Brook University, Stony Brook, New York

David C. Lee, MD
Clinical Associate Professor, New York University School of Medicine, New York, New York; Director of Research, Department of Emergency Medicine, North Shore University Hospital, Manhasset, New York

Jill F. Lehmann, MD, MPH
Assistant Professor, Northwestern University Feinberg School of Medicine; Attending Physician, Northwestern Memorial Hospital, Chicago, Illinois

E. Brooke Lerner, PhD
Associate Professor, Medical College of Wisconsin, Milwaukee, Wisconsin

Michael D. Levine, MD
Department of Medical Toxicology, Banner Good Samaritan Hospital Medical Center, Phoenix, Arizona

Roger J. Lewis, MD, PhD
Professor, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Vice Chair, Academic Affairs, Department of Emergency Medicine, Harbor-University of California at Los Angeles Medical Center, Torrance, California
Contributors

Michelle Lin, MD
Associate Clinical Professor of Emergency Medicine, University of California at San Francisco; San Francisco General Hospital, Department of Emergency Medicine, San Francisco, California

Louis J. Ling, MD
Professor, Emergency Medicine and Pharmacy and Associate Dean for Graduate Medical Education, University of Minnesota Medical School; Associate Medical Director for Education, Hennepin County Medical Center; Senior Associate Medical Director, Hennepin Regional Poison Center, Minneapolis, Minnesota

Ari M. Lipsky, MD, MS
Assistant Professor, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Attending Physician, Department of Emergency Medicine, Harbor-University of California at Los Angeles Medical Center, Torrance, California

Eve D. Losman, MD
Assistant Professor, Associate Program Director, Department of Emergency Medicine, University of Michigan Medical School, University of Michigan Health System, Ann Arbor, Michigan

Mark J. Lowell, MD
Associate Professor of Emergency Medicine, University of Michigan Medical School; Medical Director, Survival Flight, University of Michigan Health System, Ann Arbor, Michigan

Douglas W. Lowery III, MD
Associate Professor of Emergency Medicine, Emory University School of Medicine; Vice Chair of Clinical Operations, Department of Emergency Medicine, Emory Healthcare, Atlanta, Georgia

Binh T. Ly, MD, FACEP, FACMT
Associate Professor, University of California, San Diego; Director, Emergency Medicine Residency; Director, Medical Toxicology Fellowship, Division of Medical Toxicology, University of California at San Diego Medical Center, San Diego, California

Everett T. Lyn, MD, MSc
Assistant Professor, Harvard Medical School, Boston, Massachusetts; Chairman, Department of Emergency Medicine, North Shore Medical Center, Salem, Massachusetts

Malcolm Mahadevan, MD, MBBS (Singapore), MRCP (UK), FRCSEd (A&E), FAMS
Senior Clinical Lecturer, Yong Loo Lin School of Medicine, National University of Singapore; Clinical Director and Senior Consultant, Emergency Department, National University Hospital, Singapore

Brian D. Mahoney, MD
Associate Professor, Department of Emergency Medicine, University of Minnesota; Medical Director, Emergency Medical Services, Hennepin County Medical Center, Minneapolis, Minnesota

Thomas Mailhot, MD
Assistant Professor of Clinical Emergency Medicine, University of Southern California, Keck School of Medicine; Assistant Residency Director, Residency in Emergency Medicine, Los Angeles County and University of Southern California Medical Center, Los Angeles, California

William K. Mallon, MD, FACEP
Associate Professor of Clinical Emergency Medicine, Keck School of Medicine at the University of Southern California; Director, Division of International Emergency Medicine, LAC and USC Medical Center, Los Angeles, California

Gerald E. Maloney, Jr, DO
Assistant Professor, Department of Emergency Medicine, Case Western Reserve University; Attending Director of Medical Toxicology, Department of Emergency Medicine, MetroHealth Medical Center, Cleveland, Ohio

Diku P. Mandavia, MD, FACEP, FRCPC
Clinical Associate Professor of Emergency Medicine, Keck School of Medicine, University of California at Los Angeles; Attending Staff Physician, Department of Emergency Medicine, Cedars-Sinai Medical Center, Los Angeles, California

Mariann Manno, MD
Associate Professor, Clinical Pediatric and Emergency Medicine, University of Massachusetts Medical School; Division Director, Pediatric Emergency Services; Director, Pediatric Emergency Department and PediPlace, Children’s Medical Center, University of Massachusetts Memorial Hospital, Worcester, Massachusetts

Catherine A. Marco, MD, FACEP
Professor, Department of Emergency Medicine; Director of Medical Ethics Curriculum, University of Toledo College of Medicine, Toledo, Ohio

Vincent Markovchick, MD
Professor of Surgery, Division of Emergency Medicine, University of Colorado at Denver School of Medicine; Director, Department of Emergency Medicine, Denver Health Medical Center, Denver, Colorado

Marc L. Martel, MD
Associate Professor, University of Minnesota; Program Director, Emergency Medicine; Co-Program Director, Emergency Medicine/Internal Medicine, Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, Minnesota

John A. Marx, MD
Adjunct Professor of Emergency Medicine, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina; Chair, Department of Emergency Medicine, Carolinas Medical Center, Charlotte, North Carolina

Ryanne J. Mayersak, MD, MS
Assistant Professor of Emergency Medicine, The George Washington University, Washington, DC

Suzan S. Mazor, MD
Assistant Professor, Pediatrics, University of Washington; Attending Physician, Seattle Children’s Hospital, Seattle, Washington
Maureen McCollough, MD, FACEP, FAAEM
Associate Professor of Clinical Emergency Medicine and Pediatrics, Keck School of Medicine of USC; Medical Director, Emergency Department, Los Angeles County University of Southern California Medical Center, Los Angeles, California

Mary Pat McKay, MD, MPH
Associate Professor of Emergency Medicine and Public Health, The George Washington University; Director, Center for Injury Prevention and Control, The George Washington University, Washington, DC

L. Kendall McKenzie, MD
Assistant Professor of Emergency Medicine, The University of Mississippi School of Medicine, Jackson, Mississippi

Nathanael J. McKeown, DO
Assistant Professor, Oregon Health and Science University; Attending Physician, Portland Veteran Affairs Medical Center; Oregon Health and Science University, Portland, Oregon

John McManus, MD, MCR, FACEP, FAAEM
Director, Center for Pre-Deployment Medicine, U.S. Army Medical Department Center and School, Fort Sam Houston; EMS Fellowship Program Director, San Antonio Uniformed Services Health Education Consortium; Medical Director, Fort Sam Houston and Camp Bullis Fire Department; Clinical Associate Professor, Emergency Medicine, University of Texas Health Science Center, San Antonio, Texas

David B. McMicken, MD, FACEP
Regional Medical Director, TEAM Health, Southeast, Emergency Services, The Medical Center, Columbus, Georgia

Kemyed K. McQuillen, MD
Attending Physician, Central Maine Medical Center, Lewiston, Maine

Harvey W. Meislin, MD
Professor of Emergency Medicine, The University of Arizona College of Medicine; Department Head of Emergency Medicine, University Medical Center; Director, Arizona Emergency Medicine Research Center, Tucson, Arizona

Frantz R. Melio, MD, FACEP
Assistant Clinical Professor, Department of Emergency Medicine, University of New Mexico, Albuquerque, New Mexico; President, Physician Practices, CHRISTUS–St. Vincent Regional Medical Center, Santa Fe, New Mexico

William J. Meurer, MD
Clinical Lecturer, Departments of Emergency Medicine and Neurology, University of Michigan at Ann Arbor, Ann Arbor, Michigan

Nathan W. Mick, MD
Assistant Professor, University of Vermont College of Medicine, Burlington, Vermont; Director, Pediatric Emergency Medicine, Department of Emergency Medicine, Maine Medical Center, Portland, Maine

James R. Miner, MD
Associate Professor of Emergency Medicine, University of Minnesota Medical School; Research Director, Department of Emergency Medicine, Hennepin County Medical Center, Minneapolis, Minnesota

Connie Mitchell, MD, MPH
Assistant Clinical Professor, Department of Internal Medicine, School of Medicine, University of California at Davis, Davis, California; Policy Development, Maternal, Child, and Adolescent Health, California Department of Public Health, Sacramento, California

Gregory P. Moore, MD, JD
Attending Physician, Emergency Medicine Residency, Madigan Army Medical Center, Tacoma, Washington

Gregory J. Moran, MD, FACEP, FIDSA
Professor of Medicine, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Department of Emergency Medicine and Division of Infectious Diseases, Olive View–University of California at Los Angeles Medical Center, Sylmar, California

Laurie J. Morrison, MD, MSc, FRCPCH
Professor of Emergency Medicine, Department of Medicine, University of Toronto; Director, Clinician Scientist, Keenan Research Centre, Li Ka Shing Knowledge Institute, St. Michael's Hospital, Toronto, Ontario, Canada

Robert L. Muelleman, MD, FACEP
Chief of Emergency Medicine, University of Nebraska Medical Center, Omaha, Nebraska

Lindsay Murray, MD, MBBS, FACEM
Clinical Associate Professor, University of Western Australia, Perth, Western Australia; Consultant Emergency Physician and Clinical Toxicologist, Sir Charles Gairdner Hospital, Perth, Western Australia

Michael F. Murphy, MD, FRCPC
Professor and Chair, Department of Anesthesia; Professor of Emergency Medicine, Dalhousie University; Chief, Department of Anesthesia, Capital Health District Health Authority, Halifax, Nova Scotia, Canada

Vinay M. Nadkarni, MD, MS
Endowed Chair, Pediatric Critical Care Medicine, University of Pennsylvania School of Medicine; Associate Professor, Anesthesia, Critical Care and Pediatrics, University of Pennsylvania School of Medicine, Director, Center for Stimulation, Advanced Education and Innovation, Endowed Chair, Pediatric Critical Care Medicine, Department of Anesthesiology and Critical Care Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania

Yoko Nakamura, MD
Emergency Medicine Resident, Oregon Health and Science University, Portland, Oregon

Lewis S. Nelson, MD
Associate Professor of Emergency Medicine; Director, Fellowship in Medical Toxicology, New York University School of Medicine; Associate Director, New York City Poison Control Center, New York, New York

Robert W. Neumar, MD, PhD
Associate Professor of Emergency Medicine, University of Pennsylvania School of Medicine; Associate Director, Center for Resuscitation Science, University of Pennsylvania School of Medicine, Department of Emergency Medicine, Hospital of the University of Pennsylvania, Philadelphia, Pennsylvania
Edward J. Newton, MD
Professor, Emergency Medicine; Chair, Department of Emergency Medicine, Keck School of Medicine, Los Angeles; Chair, Department of Emergency Medicine, LAC and USC Medical Center, Los Angeles, California

Kim Newton, MD, FACEP
Assistant Professor of Emergency Medicine, Department of Emergency Medicine, Keck School of Medicine, University of Southern California, Los Angeles, California

James T. Niemann, MD
Professor of Medicine, The David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Senior Physician Specialist, Medicine/Emergency Medicine, Department of Emergency Medicine, Harbor-University of California at Los Angeles Medical Center, Torrance, California

Richard M. Nowak, MD, MBA
Clinical Professor, Department of Emergency Medicine, Wayne State University School of Medicine, Detroit, Michigan; Clinical Associate Professor, Department of Emergency Medicine, University of Michigan School of Medicine, Ann Arbor, Michigan; Past Chair, Department of Emergency Medicine, Henry Ford Health System, Detroit, Michigan

John F. O'Brien, MD
Associate Professor of Emergency Medicine, University of Florida College of Medicine, Gainesville, Florida; Associate Professor of Emergency Medicine, University of South Florida College of Medicine, Tampa, Florida; Associate Residency Director, Department of Emergency Medicine, Orlando Regional Medical Center, Orlando, Florida

Jonathan S. Olshaker, MD
Professor and Chair, Department of Emergency Medicine, Boston University School of Medicine; Chief, Department of Emergency Medicine, Boston Medical Center, Boston, Massachusetts

Edward J. Otten, MD, FACMT, FAWM
Professor of Emergency Medicine and Pediatrics; Director, Division of Toxicology, University of Cincinnati College of Medicine, Cincinnati, Ohio

Leslie C. Oyama, MD
Assistant Clinical Professor, University of California at San Diego, Department of Emergency Medicine, University of California at San Diego School of Medicine, San Diego, California

Daniel J. Pallin, MD, MPH
Assistant Professor, Medicine (Emergency Medicine); Assistant Professor of Pediatrics, Harvard Medical School; Research Director, Department of Emergency Medicine, Brigham and Women’s Hospital; Attending Physician, Division of Emergency Medicine, Children’s Hospital Boston, Boston, Massachusetts

Paul M. Paris, MD, FACEP, LLD(Hon)
Professor and Chair, Department of Emergency Medicine, University of Pittsburgh School of Medicine; Chief Medical Officer, Center for Emergency Medicine of Western Pennsylvania, Pittsburgh, Pennsylvania

Debra Perina, MD
Associate Professor, Emergency Medicine, University of Virginia; Director, Division of Prehospital Care, University of Virginia Medical Center, Charlottesville, Virginia

Andrew D. Perron, MD
Professor of Emergency Medicine, University of Vermont School of Medicine, Burlington, Vermont; Emergency Medicine Residency Program Director, Maine Medical Center, Portland, Maine

Shawna J. Perry, MD
Associate Professor, Associate Chair, Department of Emergency Medicine, Virginia Commonwealth University School of Medicine; Director for Patient Safety Systems Engineering, Virginia Commonwealth University Health Systems, Richmond, Virginia

Michael A. Peterson, MD
Associate Professor of Medicine, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Vice Chair, Clinical Affairs, Department of Emergency Medicine, Harbor-University of California at Los Angeles Medical Center, Torrance, California

James A. Pfaff, MD
Assistant Professor, Uniformed Services University of the Health Sciences, Bethesda, Maryland; Emergency Medicine Residency, Department of Emergency Medicine, San Antonio Uniformed Health Education (SAUSHEC), Brooke Army Medical Center, Fort Sam Houston, Houston, Texas

Sharon Pfeil, MD
Associate Professor, Departments of Anesthesiology and Emergency Medicine, University of Mississippi Medical Center, Jackson, Mississippi

Melissa Platt, MD
Assistant Professor, University of Louisville, Louisville, Kentucky

Michael Alan Polis, MD, MPH
Clinical Professor, Emergency Medicine, George Washington University Medical School, Washington, DC; Attending Physician, Division of Intramural Research, Warren Grant Magnuson Clinical Center, Bethesda, Maryland

Charles V. Pollack, Jr., MD, MA, FACEP, FAAEM, FAHA
Professor of Emergency Medicine, University of Pennsylvania School of Medicine; Chairman, Department of Emergency Medicine, Pennsylvania Hospital, Philadelphia, Pennsylvania

Timothy G. Price, MD
Associate Professor, Department of Emergency Medicine, University of Louisville, Louisville, Kentucky

Thomas B. Purcell, MD
Adjunct Assistant Clinical Professor, David Geffen School of Medicine at University of California at Los Angeles, Los Angeles, California; Attending Faculty, Department of Emergency Medicine, Kern Medical Center, Bakersfield, California
Contributors

Prasanthi Ramanujam, MD, MAS, MBBS
Assistant Professor, University of California at San Francisco; Attending Physician, Department of Emergency Medicine, University of California at San Francisco Medical Center, San Francisco, California

Preface to the Seventh Edition

We are pleased to provide this 7th edition of *Rosen’s Emergency Medicine: Concepts and Clinical Practice*, now in its 28th year of existence, and wish to recite several changes intended to enhance its content, readability, and purpose. The textbook has been converted into two volumes and reduced in size by more than 500 pages. This was accomplished with judicious editing but mostly through the transfer of the entire bibliography onto the book’s website at expertconsult.com, where the full text is available online, along with an image library, Q&A, and updates. The number of chapters is virtually unchanged while the number of annotations per chapter has been expanded. More importantly, we have strived to render the textbook as strongly evidenced based as possible through reliance on the vigilant selection of high-quality and recent references. We will continue to add online updates, wherein recent journal articles selected by the senior editors are abstracted and electronically plugged into the margins of the relevant area of the existing web-based version of the book. We also have the good fortune of adding numerous authors who are authoritative in the subjects about which they write as well as a new team that has composed a Question and Answer compendium. Much of the artwork and the format have been reworked and many of the photographs, including radiographs, have been updated.

We are grateful to many. The authors have committed their many hours and substantive expertise to lay the foundation. The editors have performed yeoman’s work to maintain consistency in templating each chapter and to help assure accuracy and clarity. We thank Judy Fletcher, our Publishing Director; Stefanie Jewell-Thomas, our Acquisitions Editor; and Dee Simpson, our Developmental Editor; for listening thoroughly and suggesting wisely and for all their work behind the scenes. We are most appreciative for the terrific support from our administrative assistants, Tricia Wyatt and Gail Franklin (JAM), Maria Figueroa (RSH), and Diane Pugh and Janice Bingham (RMW). We could not have committed the requisite time and energy to this labor of great love were we without the encouragement and buoying up from our families. Finally, we thank you, Peter, for making all this possible just because you chased a dream three decades ago.

*John A. Marx*

*Robert S. Hockberger*

*Ron M. Walls*
From the vision and foresight of a few physicians who perceived the need for a unique, disciplined, sensitive approach to the identification and stabilization of patients threatened with loss of life or limb, emergency medicine has rapidly developed into an exciting, academically recognized medical specialty. This textbook is dedicated to those who have accepted its responsibilities, challenges, and excitements.

We have attempted to define in depth the material on which our practice is based. There have been a number of efforts to write about emergencies, but we believe that this is the first to call solely on those people who themselves practice the specialty. In every chapter theory and knowledge pertinent to the practice of emergency medicine are presented.

This book is not an easy one; it was written based on published literature, not anecdote or prejudice. In many instances where the data are not available, both sides are presented with a suggested practice. The book is intended for all with a serious interest in or a need to know emergency medicine, including those who do not practice full-time emergency medicine, as well as the dedicated specialists who do.

The book is organized into two main sections—trauma and nontrauma. This division is artificial but does correspond to the first major decisions made in patient evaluations, because trauma usually affects individual anatomic structures, whereas nontrauma is more likely to affect systems.

Despite this artificial separation, long and detailed discussion and instruction to authors concerning content and style ensued. We realize that we could not tap all available talent for contributions to the book, but we have made an effort to represent different schools of thought and regions of the country.

There are deliberate omissions; for example, we elected not to include any procedures. There was not enough room to create an atlas, but it was our desire to cover the chosen topics in detail. No effort has been made to address administration, management, disaster planning, or technical requirements of emergency medicine supplies or design. Prehospital care has been included only as it related to individual topics, not as suggested protocol or from the vantage point of technician training programs.

It would be impossible to write a book this long and present nothing controversial. In fact we ourselves find sections we cannot totally accept, but in the process of working with multiple authors, we cannot with intellectual honesty put ideas into their material. We have, however, achieved our goal of presenting an in-depth vision of emergency medicine. We hope you will find the reading of this book as stimulating and enjoyable as we have found in its creation.

Acknowledgments

To all my editorial colleagues, especially Ron and Bob, as well as our authors, all of whose extraordinary and collective efforts created this edition; to my wife, Karin, for her immeasurable love and support; and to my children, Conner and Shelby, who have enriched my heart and soul beyond description.

JAM

To my mentors, my colleagues, and my students, who together comprised my professional family over the past 30 years, for their inspiration, friendship, and support; and to Patty, who brought beauty, love, and balance to my life.

RSH

With humble thanks to Peter, for his enduring friendship, for his great vision in the creation of an extraordinary specialty, and for his selfless mentorship of so many of its present and future leaders; to John and Bob, for being the engine of this amazing and rewarding collaboration; to the editors and authors, who give so freely of their precious time to help to bring so much to so many; to my amazingly resilient, loving, and supportive wife, Barb, and to my children, Andrew, Blake, and Alexa, whose love and intellectual energy inspire me.

RMW

To my father, James J. Adams, whose strength will forever inspire me; to my mother, Rita A. Adams, whose devotion to family will forever guide me; and to the many other members of my family: Cecelia, Joe, Jeff, Liz, Rob, David, Nicholas, Gregory, Leah, Katherine, Sydney, and Trent, whose support I rely on.

JGA

To all my former residents over the past 28 years from both Cincinnati and Michigan. I have been privileged to work with the best and I have learned a lot from all of you. I have to thank my children, David, Blake, and Anna, for keeping me thinking young and teaching me lots about life and family. Most of all, thanks to my wife and best friend, Mary, for her love and support over the past 33 years. She makes it all worthwhile.

WGB

To my family, friends, students, and teachers. I am continuously amazed, grateful, and humbled by your support and encouragement. Thank you.

MHB

To Joanna, Megan, and Julia and our dual-phase marriage; kind of “pre-Rosen” and now four editions together. May you never be tempted to join the literary “first-wives club.”

DFD

I dedicate this book to my husband, David, and our children, Sarah, Jeremiah, and Katie—for their patience, love, and support.

MGH

To emergency medicine residents and faculty everywhere in their constant pursuit of knowledge but especially those at Hennepin County Medical Center for continuing to teach me. I am grateful to my parents, Rose and Joseph, for their commitment to education. Special thanks to Eric, Ali, Amanda, and, most of all, Beth for their love, patience, and understanding.

LJL

I would like to thank my teachers—my parents and my children, professors and patients, colleagues and students—who have patiently taught me about medicine and life; and my steadfast companion and wife, Lynda, who has made the pursuit of wisdom possible.

EJN
PART I

Fundamental Clinical Concepts
PERSPECTIVE

Airway management is the cornerstone of resuscitation and is a defining skill for the specialty of emergency medicine. The emergency physician has primary responsibility for management of the airway. All techniques of airway management lie within the domain of emergency medicine. Rapid sequence intubation (RSI) with direct laryngoscopy is the most commonly used method for emergency intubation, but emergency airway management includes various intubation maneuvers, use of ancillary devices, approaches to the difficult airway, and rescue techniques when intubation fails.

Since the first reported use of neuromuscular blocking agents (NMBAs) in the emergency department (ED) by emergency personnel in 1971, there has been progressive sophistication of emergency airway techniques, pharmacologic agents, and special devices used to facilitate intubation. In the 1990s, RSI was widely adopted as the method of choice for most emergency intubations in the ED, and increasing attention has focused on identification and management of anticipated difficult intubation.

PATHOPHYSIOLOGY

Decision to Intubate

A decision to intubate should be based on careful assessment of the patient with respect to three essential criteria: (1) failure to maintain or protect the airway, (2) failure of ventilation or oxygenation, and (3) the patient’s anticipated clinical course and likelihood of deterioration.

Failure to Maintain or Protect the Airway

A patent airway is essential for adequate ventilation and oxygenation. If the patient is unable to maintain the airway, patency must be established by artificial means, such as repositioning, chin lift, jaw thrust, or insertion of an oral or nasal airway. Likewise, the patient must be able to protect against aspiration of gastric contents, which carries significant morbidity and mortality. Traditionally, the presence or absence of a gag reflex has been advocated as a reliable indicator of the patient’s ability to protect the airway, but the gag reflex is absent in 12 to 25% of normal adults, and there is no evidence that its presence or absence corresponds to airway protective reflexes or the need for intubation. Testing the gag reflex in an obtunded, supine patient is unlikely to yield useful information with respect to the need to intubate and may precipitate vomiting. The patient’s ability to swallow or handle secretions is a more reliable indicator of airway protection.

The recommended approach is to evaluate the patient’s ability to phonate in response to voice command or query (which provides information about level of consciousness and voice quality), level of consciousness, and ability to manage his or her own secretions (e.g., pooling of secretions in the oropharynx, absence of swallowing spontaneously or to command.) In general, a patient who requires a maneuver to establish a patent airway or who easily tolerates an oral airway probably requires intubation for protection of that airway, unless a temporary or readily reversible condition, such as opioid overdose, is present.

Failure of Ventilation or Oxygenation

Ventilatory failure that is not reversible by clinical means or increasing hypoxemia that is not adequately responsive to supplemental oxygen is a primary indication for intubation. This assessment is clinical and includes evaluation of the patient’s general status, oxygenation by pulse oximetry, and changes in the ventilatory pattern. Continuous capnography also can be helpful, but is not essential if oximetry readings are reliable. Arterial blood gases (ABGs) generally are not required to determine the patient’s need for intubation. In most circumstances, clinical assessment, including pulse oximetry with or without capnography, and observation of improvement or deterioration lead to a correct decision. ABG results are rarely helpful, may cause delay in intubating a deteriorating patient, and may be misleading, so, if obtained, they must be interpreted carefully in the context of the patient’s clinical status. Patients who are clinically improving despite severe or worsening ABG alterations may not require intubation, whereas a rapidly tiring patient may require intubation when ABG values are only modestly disturbed or even improving.

Regardless of the underlying cause, the need for mechanical ventilation generally mandates intubation. External mask devices increasingly have been used to provide assisted mechanical ventilation without intubation (see Chapter 2), but despite these advances, most patients who need assisted ventilation or positive pressure to improve oxygenation require intubation.

**Anticipated Clinical Course**

Certain conditions indicate the need for intubation even in the absence of frank airway, ventilatory, or oxygenation failure. These conditions are characterized by a moderate to high likelihood of predictable deterioration that would require airway intervention. Intubation may be indicated relatively early in the course of severe cyclic antidepressant overdose. Although the patient is awake, protecting the airway, and exchanging gas well, intubation is advisable to guard against the strong likelihood of clinical deterioration, which can occur relatively abruptly and includes coma, seizure, cardiac dysrhythmia or arrest, and possible aspiration of activated charcoal or gastric contents.

Significant multiple trauma, with or without head injury, may be an indication for intubation. Many of these patients are ventilating normally through a patent airway, and oxygen levels frequently are normal or supernormal with supplemental oxygen. Despite this, anticipated deterioration, loss of the ability to protect the airway, the need for invasive and painful procedures, or the need for studies outside the ED (e.g., computed tomography, angiography) may mandate intubation. A patient with penetrating neck trauma may present with a patent airway and adequate gas exchange. Nevertheless, early intubation is advisable with any evidence of vascular or direct airway injury because these patients tend to deteriorate and because increasing hemorrhage or swelling in the neck tends to both compromise the airway and confound later attempts at intubation.

Although these indications for intubation may seem quite different and individualized, the common thread is the anticipated clinical course over time. In each circumstance, it can be anticipated that future events will compromise either the patient’s ability to maintain and protect the airway or the patient’s ability to oxygenate and ventilate. A similar thought process is applied to any patient who will be leaving the ED for diagnostic studies (e.g., angiography) or who may be transported to another facility. If it seems clinically likely that the patient may deteriorate, then “preemptive” intubation is the prudent course.

**Identification of the Difficult Airway**

In most patients, even in the ED’s dynamic and unpredictable environment, intubation is technically easy and straightforward. In large ED studies, overall intubation failure rates are less than 1% for medical intubations and less than 3% in trauma patients. Intubation failure occurs in approximately 1 in 200 to 1 in 2000 elective general anesthesia cases. Bag-mask ventilation (BMV) is difficult in approximately 1 in 50 general anesthesia patients, and impossible in approximately 1 in 600. BMV is difficult, however, in up to one third of patients in whom intubation failure occurs, and difficult BMV-makes the likelihood of difficult intubation four times greater and the likelihood of impossible intubation 12 times greater. The combination of failure of intubation and failure of BMV in elective anesthesia practice is estimated to be exceedingly rare: 1 in 5000 to 1 in 20,000 elective anesthesia patients. These numbers cannot be applied directly to the ED situation, where patient selection cannot occur (as with a preanesthetic visit), but are reassuring in that they indicate a high degree of safety if a preintubation analysis of factors predicting difficult intubation is undertaken.

The emergency nature of the patient’s presentation often precludes postponement of the intubation, even for a short time, but knowledge of the difficulties presented by the patient’s airway permits thoughtful planning and preparation for possible intubation failure. Preintubation assessment should evaluate the patient for difficult intubation, difficult BMV, difficult ventilation using an extraglottic device (EGD, such as a laryngeal mask airway, see later discussion) and difficult cricothyrotomy. Knowledge of all four domains is crucial to successful planning.

Neuromuscular paralysis should be avoided in patients for whom a high degree of intubation difficulty is predicted, unless the administration of the NMBA is part of a planned approach to the difficult airway. This approach may include use of a double setup, in which an alternative approach, such as cricothyrotomy, is simultaneously prepared.

Preintubation evaluation should be as comprehensive as clinical circumstances permit. A systematic approach to the patient is required.

**Difficult Direct Laryngoscopy: LEMON**

Most of the difficult airway markers discussed in the anesthesia and emergency medicine literature have not been scientifically validated. Nevertheless, a methodical approach can be used to evaluate the patient, based on the accepted markers of difficult intubation by direct laryngoscopy. One such approach uses the mnemonic *LEMON* (Box 1-1).

**L—Look Externally.** The patient first should be examined for external markers of difficult intubation, which are determined based simply on the intubator’s clinical impression. For example, the severely bruised and bloodied face of a combative trauma patient, immobilized in a cervical collar on a spine board, might (correctly) invoke an immediate appreciation of anticipated difficult intubation. Subjective clinical judgment can be highly specific (>90%), but insensitive and so must be augmented by other evaluations.

**E—Evaluate 3-3-2.** The second step in the evaluation of the difficult airway is to assess the patient’s anatomy to determine his or her suitability for direct laryngoscopy. Direct laryngoscopy requires the ability to visualize the glottis by direct vision through the mouth, using alignment of the oral, pharyngeal, and laryngeal axes. Visualization requires that the mouth open adequately, that the submandibular space be adequate to accommodate the tongue, and that the larynx be positioned low enough in the neck to be accessible. These relationships have been explored in various studies by external measurement of mouth opening, oropharyngeal size, neck movement, and thyromental distance. The “3-3-2 rule” is an effective summary of these geometric evaluations. The 3-3-2 rule requires that the patient be able to place 3 of his or her own fingers between the open incisors, 3 of his or her own fingers along the floor of the mandible beginning at the mentum, and 2 fingers from the laryngeal prominence to the floor of

mandible (Fig. 1-1). A patient with a receding mandible and high-riding larynx can be impossible to intubate using direct laryngoscopy. Most patients are not sufficiently cooperative for such an evaluation, and the operator compares his or her fingers with the patient’s fingers to estimate the sizes for the three tests.

**M—Mallampati Scale.** Oral access is assessed using the Mallampati scale (Fig. 1-2). Visibility of the oral pharynx ranges from complete visualization, including the tonsillar pillars (class I), to no visualization at all, with the tongue pressed against the hard palate (class IV). Class I and class II predict adequate oral access, class III predicts moderate difficulty, and class IV predicts a high degree of difficulty. A recent meta-analysis confirmed that the four-class Mallampati score performs well as a predictor of difficult laryngoscopy (and, less so, difficult intubation), but that the Mallampati score, alone, is not a sufficient assessment tool.

**O—Obstruction or Obesity.** Upper airway (supraglottic) obstruction may make visualization of the glottis, or intubation itself, mechanically impossible. Conditions such as epiglottitis, laryngeal tumor, Ludwig’s angina, neck hematoma, or glottic polyps can compromise laryngoscopy, passage of the endotracheal tube (ETT), BMV, or all three. Physical examination for airway obstruction is combined with assessment of the patient’s voice to satisfy this evaluation step. There is conflicting evidence regarding whether obesity is itself an independent marker of difficult intubation or whether patients with obesity simply are more likely to have other markers of difficult intubation. Regardless, obese patients generally are more difficult to intubate than their non-obese counterparts, and preparations must account both for this, and for the more rapid oxyhemoglobin desaturation and increased difficulty with ventilation using bag and mask or an EGD (see below) that will occur.

**N—Neck Mobility.** Neck mobility is essential for the repositioning of the angled axes of the upper airway in order to permit direct visualization of the glottis. Neck mobility is assessed by having the patient flex and extend the head and neck through a full range of motion. Neck extension is the most important motion, and simple extension may be as effective as the “sniffing” position in achieving an optimal laryngeal view. A recent study also found that the “extension-extension” position, in which the neck is extended on the body (opposite of the sniffing position) with the head extended on the neck, provides superior laryngeal views to the sniffing position. Modest limitations of motion do not seriously impair laryngoscopy, but severe loss of motion, as can occur in ankylosing spondylitis or rheumatoid arthritis, for example, may render laryngoscopy impossible. Cervical spine immobilization in trauma artificially reduces cervical spine mobility and predicts a more difficult laryngoscopy, but direct laryngoscopy is still highly successful in this group of patients.
Identification of a difficult intubation does not preclude use of an RSI technique (see Fig. 1-7). The crucial determination is whether the clinician judges that the patient has a reasonable likelihood of intubation success, despite the difficulties identified, and that ventilation with a bag and mask or an EGD will be successful in the event that intubation fails (hence the value of the BMV and EGD assessments; see Boxes 1-2 and 1-3).

**Difficult Bag-mask Ventilation: MOANS**

Attributes of difficult BMV have largely been validated and can be summarized with the mnemonic MOANS (see Box 1-2). Difficulty with mask seal; obstruction (particularly supraglottic obstruction, but can be present anywhere in the airway) or obesity (because of redundant upper airway tissues, chest wall weight, and resistance of abdominal mass); advanced age (best judged by the physiologic appearance of the patient, but age older than 55 years increases risk); edentulousness (“no teeth”), which independently interferes with mask seal; and stiffness or resistance to ventilation (e.g., asthma, chronic obstructive pulmonary disease, pulmonary edema, restrictive lung disease, term pregnancy) all cause or contribute to increased difficulty with BMV. The difficulty with BMV of the edentulous patient is the basis of the adage: “Remove dentures to intubate, leave them in to bag-mask ventilate.” The wisdom of this approach recently was validated yet again.29

**Difficult Extraglottic Device Placement: RODS**

Placement of an EGD, such as a laryngeal mask airway, a Combitube, or a similar upper airway device often can facilitate ventilation, and convert a “can’t intubate, can’t oxygenate” situation to a “can’t intubate, can oxygenate” situation, which allows time for more careful planning of the rescue of a failed airway (see following section.) Difficulty achieving placement or ventilation using an EGD is predicted by the mnemonic “RODS.” Fortunately, if the clinician has already performed the LEMON and MOANS assessments, only the “D” for distorted anatomy remains to be evaluated (see Box 1-3).

**Difficult Cricothyrotomy**

Difficult cricothyrotomy can be anticipated whenever there is disturbance of the ability to locate and access the landmarks of the anterior airway via the neck. Prior surgery; the presence of hematoma, anatomic disruption, tumor, or abscess; scarring (as from radiation therapy or prior injury); or obesity, edema, or subcutaneous air each has the potential to make cricothyrotomy more difficult. The landmarks for cricothyrotomy are sought and identified as part of the preintubation assessment of the patient.

**Measurement of Intubation Difficulty**

The actual degree to which an intubation is “difficult” is highly subjective, and quantification is challenging. Research has relied on laryngoscopic view to characterize the intubation difficulty, and the most widely used system is that of Cormack and Lehane, which grades laryngoscopy according to the extent to which laryngeal and glottic structures can be seen.

Grade 1 laryngoscopy, the entire glottic aperture is seen. Grade 2 laryngoscopy visualizes only a portion of the glottis (arytenoid cartilages alone or arytenoid cartilages plus part of the vocal cords). Grade 3 laryngoscopy visualizes only the epiglottis. In grade 4 laryngoscopy, not even the epiglottis is visible.

Research conducted on elective anesthesia patients suggests that true grade 4 laryngoscopy, which is associated with impossible intubation, occurs in less than 1% of patients. Grade 3 laryngoscopy, which represents extreme intubation difficulty, is found in less than 5% of patients. Grade 2 laryngoscopy, which occurs in 10 to 30% of patients, can be subdivided further into grade 2a, in which arytenoids and a portion of the vocal cords are seen, and grade 2b, in which only the arytenoids are seen. Intubation failure occurs in 67% of grade 2b cases but in only 4% of grade 2a cases.30 Approximately 80% of all grade 2 laryngoscopies are grade 2a; the rest are grade 2b. A grade 1 view is associated with virtually 100% intubation success. An alternative system, the POGO (percentage of glottic opening) also has been proposed and validated, but is not widely used or studied.31

**Confirmation of Endotracheal Tube Placement**

The most serious complication of endotracheal intubation is unrecognized esophageal intubation with resultant hypoxic brain injury. Although direct visualization of the ETT passing through the vocal cords generally is a reliable indicator of tracheal intubation, such clinical anatomic observations are fallible, and additional means are required to ensure correct placement of the tube within the trachea. Traditional methods, such as chest auscultation, gastric auscultation, bag resistance, exhaled volume, visualization of condensation within the ETT, and chest radiography, all are prone to failure as means of confirming tracheal intubation.32 Other clinical techniques are readily available for detecting tracheal or esophageal intubation.

Immediately after intubation, the intubator should apply an end-tidal carbon dioxide (ETCO₂) detection device to the ETT and assess it through six manual ventilations. Dispos- able, colorimetric ETCO₂; detectors are highly reliable, convenient, and easy to interpret, indicating adequate CO₂ detection by color change (Figs. 1-3 and 1-4) (see Chapter 3). ETCO₂ detection is highly reliable in determining tracheal and esophageal intubation in patients with spontaneous circulation.33 These devices indicate the carbon dioxide content in exhaled
In patients with cardiopulmonary arrest, a CO2 level greater than 2% is used reliably as an indicator of esophageal intubation. This is easy and rapid. The other method of tube placement confirmation is the aspiration technique, which is based on the anatomic differences between the trachea and the esophagus. The esophagus is a muscular structure with no support within its walls. The trachea is held patent by cartilaginous rings. Vigorous aspiration of air through the ETT with the ETT cuff deflated results in occlusion of the ETT orifices by the soft walls of the esophagus, whereas aspiration after tracheal placement of the tube is easy and rapid.

Bulb or syringe aspiration devices may be used in patients with cardiac arrest who have no detectable CO2, but although such devices are highly reliable at detecting esophageal intubation (sensitivity > 95%), false-positives, in which a correctly placed tracheal tube is incorrectly identified as esophageal, can occur in up to 25% of cardiac arrest patients. Aspiration devices may be useful in the out-of-hospital setting when poor lighting hampers colorimetric ETCO2 determination. They also are good backup devices when cardiac arrest confounds attempts to assess placement using ETCO2. Detection of expired CO2 is more reliable and should be considered the standard for confirmation of tracheal placement of an ETT and for early detection of accidental esophageal intubation. Aspiration devices have a valuable, but secondary role.

Repeat laryngoscopy generally is insufficient to “confirm” that the tube is through the glottis because error and misinterpretation can occur, especially if the clinician confirming the intubation is the same person who intubated in the first place. The objective instrument (ETCO2) should be considered correct. Complete obstruction of the trachea or both main stem bronchi, which prevents ventilation of the patient with even small tidal volumes, can lead to failure to detect CO2 even when the tube is in the trachea. In the absence of known or suggested complete large airway obstruction, however, failure to detect CO2 should not be ascribed to other causes, such as severe asthma, in which the physician might postulate that adequate CO2 exchange is not occurring for physiologic reasons. Absent equipment failure, this generally does not occur, and detection failure should be equated with intubation failure.

Accordingly, ETCO2 detection, with aspiration as backup, should be considered the primary means of ETT placement confirmation. Secondary means include physical examination findings, oximetry, and radiography. The examiner should auscultate both lung fields and the epigastric area. Auscultation of typical hollow, gurgling, gastric sounds in the epigastrium is highly suggestive of esophageal intubation and should prompt consideration of immediate reintubation. Diminished or absent breath sounds on one side (usually the left side) indicate main stem bronchus intubation, in the absence of pneumothorax or an alternative cause of unilateral loss of breath sounds. Persistent, obvious leak despite positive ETCO2 detection indicates cuff malfunction or supraglottic placement of the ETT, such that the tube is in the airway, detecting CO2, but above the vocal cords. In either case (main stem bronchus intubation or supraglottic intubation), tube malpositioning can be confirmed by inspection of the depth of insertion of the tube, supplemented by chest radiography when needed. If malpositioning is detected, repositioning is indicated.

Pulse oximetry is indicated as a monitoring technique in all critically ill patients, not just those who require intubation. Oximetry is useful in detecting esophageal intubation, but
may not show a decreasing oxygen saturation for several minutes after a failed intubation because of the oxygen reservoir (preoxygenation) created in the patient before intubation. Oximetry may be particularly misleading in a spontaneously breathing patient who has had an inadvertent nasoesophageal intubation and did not have the ET\(\text{CO}_2\) measured. In this case, oxygen saturation may be preserved because of spontaneous respirations, but catastrophe can ensue if the patient is later paralyzed or heavily sedated in the mistaken belief that the tube is in the trachea.

Although chest radiography is universally recommended after ETT placement, its primary purpose is to ensure that the tube is well positioned below the cords and above the carina. A single anteroposterior chest radiograph is not sufficient to detect esophageal intubation, although esophageal intubation may be detected if the ETT is clearly outside the air shadow of the trachea. In cases where doubt persists, a fiberoptic scope can be passed through the ETT to identify tracheal rings, a “gold standard” for confirmation of tracheal placement.

### MANAGEMENT

#### Approach to Intubation

After it is determined that the patient requires intubation, an approach must be planned. Algorithms for emergency airway management have been developed and provide a useful guide, both for planning intubation and for rescue in the event of intubation failure. The algorithm in Figure 1-5 assumes that a decision to intubate has been made and outlines such an approach. The approach is predicated on two key determinations that must be made before active airway management is begun (see Fig. 1-5). The first determination is whether the patient is in cardiopulmonary arrest or a state near to arrest and is predicted to be unresponsive to direct laryngoscopy. Such a patient (agonal, near death, circulatory collapse) is called a “crash airway” patient for the purposes of emergency airway management and is treated using the crash airway algorithm by immediate intubation without use of drugs, supplemented by a single dose of succinylcholine if the attempt to intubate fails and the patient is felt not to be sufficiently relaxed (Fig. 1-6). Next, it must be determined whether the patient represents a difficult intubation as determined by the LEMON, MOANS, and RODS evaluations. If so, the difficult airway algorithm is used (Fig. 1-7).

For all other cases, that is, for all patients who require emergency intubation but who have neither a crash airway nor a difficult airway, RSI is recommended. RSI provides the safest and quickest method of achieving intubation in such conditions.

![Figure 1-5](https://example.com) **Figure 1-5.** Main emergency airway management algorithm. OTI, orotracheal intubation; RSI, rapid sequence intubation. patients. After administration of the RSI drugs, intubation attempts are repeated until the patient is intubated or a failed intubation is identified. If more than one intubation attempt is required, oxygen saturation is monitored continuously, and if saturation falls to 90% or less, BMV is performed until saturation is recovered for another attempt. If the clinician cannot maintain oxygen saturation with BMV, despite optimal use of a two-person, two-handed technique with an oral airway in place, a failed airway exists. This is referred to as a “can’t intubate, can’t oxygenate” situation. In addition, if three attempts at direct laryngoscopy have been unsuccessful, a failed airway exists because subsequent attempts at laryngoscopy by the same clinician are unlikely to succeed. The three failed laryngoscopy attempts are defined as attempts by an experienced clinician, using best possible patient positioning and technique. A further attempt at direct laryngoscopy by the same clinician or one of equivalent experience is advisable, unless the clinician identifies a specific situation on the third laryngoscopy that is amenable to correction, justifying a fourth attempt. Also, if the clinician ascertains after even a single attempt that intubation will be impossible (e.g., grade IV laryngoscopic view despite optimal patient positioning), a failed airway is present. The failed airway is managed according to the failed airway algorithm (Fig. 1-8).

Difficult Airway

When preintubation evaluation has identified a potentially difficult airway, a different approach is used (see Fig. 1-7). The approach is based on the fact that NMBAs should not be administered to a patient for intubation unless the clinician believes that (1) intubation is likely to be successful and (2) ventilation is likely to be successful and (2) the likelihood of successful ventilation using a bag and mask or an EGD in the event intubation is unsuccessful, and (2) the likelihood of successful ventilation by direct laryngoscopy. In some cases, a double setup can be used in which RSI is performed, but all preparations are undertaken for rescue cricothyotomy before the drugs are administered. If RSI is not advisable, an “awake” technique can be used. In this context, “awake” means that the patient continues to breathe and is able to respond to caregivers. Usually the technique involves sedation and topical anesthesia, often preceded by a drying agent, such as glycopyrrolate.

The perception of a difficult airway is relative, and many emergency intubations could be considered “difficult.” The judgment regarding whether to treat the airway as a typical emergency airway or whether to use the difficult airway algorithm is based on the degree of perceived difficulty and the individual circumstances of the case. The LEMON, MOANS, and RODS assessments provide a systematic framework to assist in identifying the potentially difficult airway.

When a difficult airway is identified, the first step is to ensure that oxygenation is sufficient to permit a planned, orderly approach (see Fig. 1-7). If oxygenation is inadequate and cannot be made adequate by supplementation with bag and mask, the airway should be considered a failed airway. The failed airway algorithm should be used because the predicted high degree of intubation difficulty combined with failure to maintain oxygen saturation is analogous to the “can’t intubate, can’t oxygenate” situation. When oxygenation is adequate, the next consideration is whether RSI is appropriate, based on the operator’s assessment of the likelihood of (1) successful ventilation using a bag and mask or an EGD in the event intubation is unsuccessful, and (2) the likelihood of successful intubation by direct laryngoscopy. In some cases, a double setup can be used in which RSI is performed, but all preparations are undertaken for rescue cricothyotomy before the drugs are administered. If RSI is not advisable, an “awake” technique can be used. In this context, “awake” means that the patient continues to breathe and is able to respond to caregivers. Usually the technique involves sedation and topical anesthesia, often preceded by a drying agent, such as glycopyrrolate.

The awake technique often is direct laryngoscopy, assisted by topical anesthesia and sedation (comparable to that for a painful procedure), with the purpose of ascertaining whether intubation using direct laryngoscopy is possible. If the glottis is adequately visualized, the patient can be intubated at that time, or, in a stable difficult airway situation, the clinician may proceed with planned RSI, now assured of intubation success. Awake laryngoscopy can be performed using a direct laryngoscope, a flexible fiberoptic scope, a videolaryngoscope, or a rigid fiberoptic scope. If the awake laryngoscopy determines that oral intubation using a standard laryngoscope would likely be unsuccessful, the patient is intubated using any of numerous techniques shown in the last box in Figure 1-7. For each of these methods, the patient is kept breathing but variably sedated and anesthetized and each of the methods results in placement of a cuffed ETT in the trachea. The choice among these methods depends on clinician experience and preference, device availability, and patient attributes.

**Failed Airway**

Management of the failed airway is dictated by an assessment of whether the patient can be oxygenated.\(^3\)\(^,\)\(^4\) If adequate oxygenation cannot be maintained, the rescue technique of first resort is cricothyrotomy (see Fig. 1-8). Multiple attempts at other methods in the context of failed oxygenation delay cricothyrotomy and place the patient at increased risk for hypoxic brain injury. If an alternative device (i.e., an EGD such as a laryngeal mask airway or Combitube) is readily at hand, however, an attempt can be made to use it simultaneously with preparations for immediate cricothyrotomy, as long as initiation of cricothyrotomy is not delayed. Only a single attempt with the EGD is recommended in this circumstance.

If adequate oxygenation is possible, several options are available for the failed airway. In almost all cases, cricothyrotomy is the definitive rescue technique for the failed airway if time (i.e., preservation of oxygenation) does not allow for other approaches or if they fail. The fundamental difference in philosophy between the difficult airway and the failed airway is that the difficult airway is planned for, and the standard is to place a cuffed ETT in the trachea. The failed airway is not planned for, and the standard is to achieve an airway that provides adequate oxygenation to avert the immediate problem of hypoxic brain injury. Some of the devices used in the failed airway (e.g., EGDs) are temporary and do not provide airway protection.

---

**THERAPEUTIC MODALITIES**

**Methods of Intubation**

Although many techniques are available for intubation of the emergency patient, four methods are most common, with RSI being the most frequently used in nonarrested patients.\(^1\)\(^,\)\(^13\)\(^,\)\(^14\)\(^,\)\(^39\)

**Rapid Sequence Intubation**

RSI is the cornerstone of modern emergency airway management and is defined as the virtually simultaneous administration of a potent sedative (induction) agent and an NMBA, usually succinylcholine, for the purpose of endotracheal intubation. This approach provides optimal intubating conditions and has long been believed to minimize the risk of aspiration of gastric contents. A systematic review of the literature in 2007 failed to prove that rapid sequence intubation results in a lower incidence of aspiration than other techniques, but the authors correctly noted that virtually no studies have ever been designed to measure this precise endpoint.\(^40\) RSI is nevertheless the most widely used technique by far for emergency intubation of patients without identifiable difficult airway attributes.\(^13\)\(^,\)\(^14\)

The central concept of RSI is to take the patient from the starting point (e.g., conscious, breathing spontaneously) to a state of unconsciousness with complete neuromuscular paralysis, then to achieve intubation without interposed assisted ventilation. The risk of aspiration of gastric contents is felt to be significantly higher for patients who have not fasted before induction. Application of positive-pressure ventilation can cause air to pass into the stomach, resulting in gastric distention and likely increasing the risk of regurgitation and aspiration.\(^41\) The purpose of RSI is to avoid positive-pressure ventilation until the ETT is placed correctly in the trachea with the cuff inflated. This requires a preoxygenation phase, during which the nitrogen reservoir in the functional residual capacity in the lungs is replaced with oxygen, permitting at least several minutes of apnea (see later discussion) in the normal adult before oxygen desaturation to 90% ensues (Fig. 1-9).\(^35\)

Use of RSI also facilitates successful endotracheal intubation by causing complete relaxation of the patient’s musculature, allowing better access to the airway.\(^39\)\(^,\)\(^36\)\(^,\)\(^37\)\(^,\)\(^42\) Finally, RSI permits pharmacologic control of the physiologic responses to laryngoscopy and intubation, mitigating potential adverse effects. These effects include further intracranial pressure (ICP) increase in response to the procedure and to the sympathetic discharge resulting from laryngoscopy (Box 1-4).\(^3\)\(^4\) RSI is a series of discrete steps, and every step should be planned (see Box 1-5).\(^3\)

**Preparation.** In the initial phase, the patient is assessed for intubation difficulty (unless this has already been done), and the intubation is planned, including determining dosages and

---

**Figure 1-9.** Desaturation time for apneic, fully preoxygenated patients. Children, patients with comorbidity, and obese patients desaturate much more rapidly than healthy, normal adults. The box on the lower right-hand side of the graph depicts time to recovery from succinylcholine, which in almost all cases exceeds safe apnea time. Note also the precipitous decline of oxygen saturation from 90% to 0% for all groups. Modified from Benumof J, et al: Critical hemoglobin desaturation will occur before return to unparalyzed state following 1 mg/kg intravenous succinylcholine. Anesthesiology 87:979, 1997.
sequence of drugs, tube size, and laryngoscope type, blade and size. Drugs are drawn up and labeled. All necessary equipment is assembled. All such patients require continuous cardiac monitoring and pulse oximetry. At least one and preferably two good-quality intravenous (IV) lines should be established. Redundancy is always desirable in case of equipment or IV access failure.

**Preoxygenation.** Administration of 100% oxygen for 3 minutes of normal, tidal volume breathing in a normal, healthy adult establishes an adequate oxygen reservoir to permit 8 minutes of apnea before oxygen desaturation to less than 90% occurs (see Fig. 1-9). The time to desaturation to less than 90% in children, obese adults, late-term pregnant women, and patients with significant comorbidity is considerably less. Desaturation time also is reduced if the patient does not inspire 100% oxygen. Nevertheless, adequate preoxygenation usually can be obtained, even in ED patients, to permit several minutes of apnea before oxygen desaturation to less than 90% occurs. In children and adults, preoxygenation is essential to the “no bagging” approach of RSI. If time is insufficient for a full 3-minute preoxygenation phase, eight vital capacity breaths using high-flow oxygen can achieve oxygen saturations and apnea times that match or exceed those obtained with traditional preoxygenation. Preoxygenation of obese patients in the head up position results in significantly longer (approximately 45 seconds) apnea time before critical saturation. Preoxygenation should be done in parallel with the preparation phase and can be started in the field for high risk patients. Oxygen saturation monitors permit earlier detection of desaturation during laryngoscopy, but preoxygenation remains an essential step in RSI.

**Pretreatment.** During this phase, drugs are administered 3 minutes before administration of the succinylcholine and induction agent to mitigate the effects of laryngoscopy and intubation on the patient’s presenting or comorbid conditions. Intubation is intensely stimulating and results in sympathetic discharge (the reflex sympathetic response to laryngoscopy), elevation of ICP in patients with ICP disturbance, and reactive bronchospasm. Bradycardia often occurs in children, particu-

7. Postintubation management

larily young children, but appears multifactorial, likely involving both parasympathetic discharge in response to airway instrumentation and perhaps some contributory effect of succinylcholine.

Pretreatment focuses on three main objectives, in certain at-risk patients. The three groups of patients at risk are those with reactive airways disease, elevated ICP, or a cardiovascular or neurovascular condition or acute event for which an acute elevation in blood pressure and heart rate might be hazardous. Patients with reactive airways disease often experience a worsening of their bronchospasm when intubated. Contrary exists regarding whether albuterol alone, lidocaine alone, or both drugs together are effective in reducing this intubation-related bronchospasm. Asthmatic patients being intubated in the ED for status asthmaticus will have received albuterol before intubation, and, pending larger studies, it is reasonable also to administer lidocaine (1.5 mg/kg) as a pretreatment drug in these cases. When an asthmatic patient is being intubated for a condition (e.g., trauma) other than acute asthma, nebulized albuterol and IV lidocaine should be given before intubation, if possible. Patients with significant cardiovascular disease (e.g., ischemic coronary disease) who are being intubated in the ED may benefit from the administration of the synthetic opioid, fentanyl, in a dose of 3 µg/kg to mitigate the release of catecholamines in response to airway manipulation. Similarly, patients with intracranial effects of laryngoscopy and intubation. Although many variations are possible for pretreatment regimens in various conditions, pretreatment can be simplified to these three basic indications (see Box 1-4).

When possible, 3 minutes should elapse between the administration of the pretreatment drug and the administration of the induction drug and NMBA. If time is insufficient to wait 3 minutes, even a reduced time may provide some benefit.

**Paralysis with Induction.** In this phase, a potent sedative agent is administered by rapid IV push in a dose capable of rapidly producing unconsciousness. This is immediately followed by rapid administration of an intubating dose of an NMBA, usually succinylcholine. It is usual to wait 45 seconds from the time the succinylcholine is given to allow sufficient paralysis to occur. (See later discussion of drugs and doses.)

**Positioning.** The patient should be positioned for intubation as consciousness is lost. Usually, positioning involves head extension, often with flexion of the neck on the body, but there is evidence that simple extension of the head alone, or extension of both the head and neck (the extension-extension position) are equivalent or superior.27,28 (See earlier discussion.) Sellick’s maneuver (application of firm backward-directed pressure over the cricoid cartilage) has long been recommended to minimize the risk of passive regurgitation and, hence, aspiration, but two recent reviews have challenged this premise.26,52 In addition, there is evidence that Sellick’s maneuver may make laryngoscopy or intubation more difficult.
in some patients. Accordingly, Sellick’s maneuver should be considered optional, applied selectively, and released or modified to improve laryngeal view or tube passage, as indicated. During this phase after administration of the induction agent and NMBA, although the patient becomes unconscious and apneic, BMV should not be initiated unless the oxygen saturation falls to 90%.

**Placement of Tube.** Approximately 45 seconds after the administration of succinylcholine, the patient is relaxed sufficiently to permit laryngoscopy; this is assessed most easily by moving the mandible to test for absence of muscle tone. The ETT is placed under direct visualization of the glottis. If the first attempt is unsuccessful, but oxygen saturation remains high, it is not necessary to ventilate the patient with a bag and mask between intubation attempts. If the oxygen saturation is approaching 90%, the patient may be ventilated briefly with a bag and mask between attempts to reestablish the oxygen reservoir. When BMV is performed, Sellick’s maneuver is advisable to minimize passage of air into the stomach. Sellick’s maneuver may be continued or released during repeat laryngoscopy, according the judgment of the clinician and the glottic view obtained. As soon as the ETT is placed, the cuff should be inflated and its position confirmed as described earlier.

**Postintubation Management.** A chest radiograph should be obtained to confirm that main stem intubation has not occurred and to assess the lungs. There is a trend away from the use of long-acting NMBA (e.g., pancuronium, vecuronium) toward optimal management using opioid analgesics and sedative agents to facilitate mechanical ventilation. (See Chapter 3.) An adequate dose of a benzodiazepine (e.g., midazolam 0.1–0.2 mg/kg, IV) and an opioid analgesic (e.g., fentanyl, 3–5 μg/kg, IV, or morphine, 0.2–0.3 mg/kg, IV) is given to improve patient comfort and decrease sympathetic response to the ETT. Appropriate use of sedation and analgesia often obviates the need for an NMBA. Table 1-1 presents a sample RSI protocol using etomidate and succinylcholine. “Zero” refers to the time at which the induction agent and succinylcholine are pushed.

**Blind Nasotracheal Intubation**

Historically, blind nasotracheal intubation (BNTI) was used extensively in the ED and out-of-hospital setting, but has fallen out of favor largely because of the superiority of RSI. Success rates have been about 80 to 90%, and high complication rates are reported, most often epistaxis or delayed or incorrect tube placement. Long-term complications (e.g., sinusitis, turbinate destruction, laryngeal perforation) are uncommon and related to multiple attempts or prolonged intubation. Basilar skull fracture and facial trauma have been considered contraindications to nasotracheal intubation because of the risk of entering the cranial vault or increasing the incidence of intracranial infection. These contraindications are not based on scientific study, however, and two small studies failed to detect a difference in complications between orally and nasally intubated facial trauma patients. Two other studies compared the success rates of RSI and BNTI performed by physicians or paramedics on helicopter services. Results differed, with one study showing essentially equivalent success rates and the other showing a significant advantage for neuromuscular blockade over BNTI. ED studies have shown superiority of RSI over BNTI. Also, the incidence and severity of oxygen desaturation are greater in BNTI than with RSI.

BNTI is a valid and useful method of intubation in the out-of-hospital setting and is still widely used by paramedics and other out-of-hospital first responders. In the ED, where NMBA and RSI are available, BNTI should be considered a second-line approach and reserved for patients in whom the presence of a difficult airway makes RSI undesirable or contraindicated and alternatives (e.g., fiberoptics) are not available. Interestingly, the old recommendation that refrigeration of the tube before use increases success of nasotracheal intubation probably is not true. To the contrary, warming the tube to 40° before use appears to facilitate easy tube passage and reduce the incidence of epistaxis. Similarly, maintaining the head in a neutral position and inflating the ETT cuff to 15 mL in the oropharynx or hypopharynx before attempting to traverse the glottis also improves the success rate. Use of BNTI in the ED has declined sufficiently, and it is doubtful that emergency medicine residents will be adequately trained in the technique.

**Awake Oral Intubation**

Awake oral intubation is a technique in which sedative and topical anesthetic agents are administered to permit management of a difficult airway. Sedation and analgesia are achieved in a manner analogous to that for painful procedures in the ED. Topical anesthesias may be achieved by spray, nebulization, or local anesthetic nerve block. After the patient is sedated and topical anesthetic has been achieved, gentle direct, video, or fiberoptic laryngoscopy is performed to determine whether the glottis is visible and intubation possible. The patient may be intubated during the laryngoscopy, or the laryngoscopy may show that oral intubation is possible, permitting safe use of RSI (see earlier discussion).

Awake oral intubation is distinct from the practice of oral intubation using a sedative or opioid agent to obtund the patient for intubation without neuromuscular blockade, which had been a typical ED practice. This latter technique can be referred to as “intubation with sedation alone” or, paradoxically, “nonparalytic RSI.” Proponents of intubation with sedation alone argue that administration of a benzodiazepine, opioid, or both provides improved access to the airway, decreases patient resistance, and avoids the risks inherent
in neuromuscular blockade. This technique actually is more hazardous than RSI, however. Intubating conditions achieved even with deep anesthesia are significantly inferior to the conditions achieved when neuromuscular blockade is used.\textsuperscript{36,37,61} The same superiority of neuromuscular blockade-assisted intubation over intubation with sedation alone has been observed in pediatric emergency medicine and in EMS care.\textsuperscript{62,63} In general, the technique of administering a potent sedative agent to obtund the patient’s responses and permit intubation in the absence of neuromuscular blockade is ill-advised and inappropriate for ETI in the ED, unless it is performed as part of an “awake” intubation as described earlier.

**Oral Intubation without Pharmacologic Agents**

The unconscious, unresponsive, near death patient may not require pharmacologic agents for intubation. If the patient is essentially dead, administration of any pharmacologic agent, including an NMBA, may needlessly delay intubation. Even an unconscious patient may retain sufficient muscle tone to render intubation difficult, however. If the glottis is not adequately visualized, administration of a single dose of succinylcholine alone may facilitate laryngoscopy. Success rates for intubating unconscious, unresponsive patients are comparable to those achieved with RSI, presumably because the patient is in a similar physiologic state (i.e., muscle relaxation, no ability to react to laryngoscopy or tube insertion).\textsuperscript{1}

**Pharmacologic Agents**

**Neuromuscular Blocking Agents**

Muscle contraction is the result of membrane depolarization, which causes massive intracellular release of calcium ions from the sarcoplasmic reticulum, leading to active contraction of myofibrils. The inciting incident is the depolarization of portions of the myocyte membrane, called the motor endplates, which are adjacent to the innervating axons. Action potentials conducted down the innervating axons cause release of the neurotransmitter acetylcholine (ACh) from the terminal axon. The ACh traverses the synaptic cleft, binds reversibly to receptors on the motor endplate, and opens channels in the membrane to initiate depolarization.

NMBA are highly water-soluble, quaternary ammonium compounds that mimic the quaternary ammonium group on the ACh molecule. Their water solubility explains why these agents do not readily cross the blood-brain barrier or placenta. The NMBA are divided into two main classes. The depolarizing agent, succinylcholine, exerts its effects by binding non-competitively with ACh receptors on the motor endplate and causing sustained depolarization of the myocyte. The other major class of NMBA comprises the competitive, or nondepolarizing, agents, which bind competitively to ACh receptors, preventing access by ACh and preventing muscular activity. The competitive agents are of two pharmacologically distinct types, steroid-based agents (aminosteroid compounds) and benzylisoquinolines. Each of these basic chemical types has distinct properties, but only the aminosteroid compounds are used in the ED.

**Succinylcholine.** Succinylcholine is a combination of two molecules of ACh. Succinylcholine is rapidly hydrolyzed by plasma pseudocholinesterase to succinylmonocholine, which is a weak NMBA, then to succinic acid and choline, which have no NMBA activity. Pseudocholinesterase is not present at the motor endplate and exerts its effects systemically before the succinylcholine reaches the ACh receptor.\textsuperscript{1} Only a small amount of the succinylcholine that is administered survives to reach the motor endplate. When attached to the ACh receptor, succinylcholine is active until it diffuses away. Decreased plasma pseudocholinesterase activity can increase the amount of succinylcholine reaching the motor endplate, prolonging succinylcholine block, but this is of little significance in the emergency setting because the prolongation of action is rarely significant, reaching only 23 minutes at the extreme.\textsuperscript{64,65}

**Uses.** Succinylcholine is rapidly active, typically producing intubating conditions within 60 seconds of administration by rapid IV bolus injection.\textsuperscript{37,66} The clinical duration of action before spontaneous respiration is 6 to 10 minutes (see Fig. 1-9).\textsuperscript{35} Full recovery of normal neuromuscular function occurs within 15 minutes. The combination of rapid onset, complete reliability, short duration of action, and absence of serious side effects maintains succinylcholine as the drug of choice for most ED intubations.\textsuperscript{1,13,50,62} The use of a competitive, or non-depolarizing, NMBA for RSI may be desirable when succinylcholine is contraindicated and in certain other settings.

**Cardiovascular Effects.** As an ACh analogue, succinylcholine binds to ACh receptors throughout the body, not just at the motor endplate. It is difficult to separate the effects of succinylcholine on the heart that are caused by direct cardiac muscarinic stimulation from those caused by stimulation of autonomic ganglia by succinylcholine and from the effects induced by the autonomic responses to laryngoscopy and intubation. Succinylcholine can be a negative chronotrope, especially in children, and sinus bradycardia may ensue after succinylcholine administration. Sinus bradycardia is treated with atropine, if necessary, but is often self-limiting. Some pediatric practitioners recommend pretreatment with atropine for children younger than 1 year old, but there is no evidence for benefit.\textsuperscript{67} Other cardiac dysrhythmias, including ventricular fibrillation and asystole, have been reported with succinylcholine, but it is impossible to distinguish the effects of the drug itself from those caused by the intense vagal stimulation and catecholamine release that accompany laryngoscopy and intubation. In addition, many of these catastrophic complications occur in critically ill patients, further confounding attempts to identify whether the illness or any particular drug or procedure is the cause.

**Fasciculations.** The depolarizing action of succinylcholine results in fine, chaotic contractions of the muscles throughout the body for several seconds at the onset of paralysis in over 90% of patients. Muscle pain occurs in approximately 50% of patients who receive succinylcholine. Although it is widely believed that muscle pains are reduced or abolished by prior administration of a defasciculating dose of a competitive NMBA, the evidence is not conclusive.\textsuperscript{68} Use of 1.5 mg/kg of succinylcholine results in less fasciculation and less myalgia than occur with 1 mg/kg.\textsuperscript{68}

**Hyperkalemia.** Succinylcholine has been associated with severe, fatal hyperkalemia when administered in specific clinical circumstances (Table 1-2).\textsuperscript{69} Although the hyperkalemia occurs within minutes after administration of succinylcholine and may be severe or fatal, the patient’s vulnerability to succinylcholine-induced hyperkalemia does not become significant until at least 5 days after the inciting injury or burn. Succinylcholine remains the agent of choice for RSI in acute burn, trauma, stroke, spinal cord injury, and intra-abdominal sepsis if intubation occurs less than 5 days after onset of the condition. If doubt exists regarding the onset time, succinylcholine should be replaced with a competitive NMBA, usually rocuronium. Denervation syndromes (e.g., multiple sclerosis, amyotrophic lateral sclerosis) can be particularly troubling, however, because the risk begins with the onset of the disease and continues indefinitely, regardless of the apparent stability of the symptoms. Patients who have denervation caused by
stroke or spinal cord injury are stabilized after 6 months, and thereafter can receive succinylcholine safely.66 Potassium release does not occur to any significant extent in the general population. Succinylcholine is not contraindicated in renal failure but probably should not be used in patients with known or presumed hyperkalaemia sufficient to manifest on the electrocardiogram. The only published series of patients with hyperkalaemia, many of whom had renal failure, failed to show a single adverse event related to succinylcholine administration.70

**Increased Intraocular Pressure.** Succinylcholine may cause a modest increase in intraocular pressure and historically has been considered relatively to absolutely contraindicated in penetrating globe injury. There is no published evidence to support this view, however, and several large series show safety when succinylcholine is used in patients with open globes. The admonition to avoid succinylcholine in open globe injuries is unjustified and should be abandoned.71

**Masseter Spasm.** Succinylcholine has been reported rarely to cause masseter spasm, primarily in children.64 The clinical significance of this phenomenon is unclear, but administration of a competitive NMBA terminates the spasm. Severe, persistent spasm should raise suspicion of malignant hyperthermia.72

**Malignant Hyperthermia.** Succinylcholine has been associated with malignant hyperthermia, a perplexing syndrome of rapid temperature rise and aggressive rhabdomyolysis. Malignant hyperthermia occurs in genetically predisposed individuals who receive certain volatile anesthetic agents or succinylcholine. The condition is extremely rare and has not been reported in the context of ED intubation. Treatment consists of cessation of any potential offending agents, administration of dantrolene (2 mg/kg IV every 5 min to a maximum dose of 10 mg/kg), and attempts to reduce body temperature by external means.72 A national malignant hyperthermia hotline is available for emergency consultation at 1-800-644-9737 (then dial zero).

**Rocuronium.** The standard recommendation to keep succinylcholine refrigerated creates problems related to its storage, timely retrieval, and ready availability on intubation carts or kits in the ED. Succinylcholine undergoes degradation beginning at the time of manufacture, and the rate of this degradation is much lower when the drug is refrigerated. Succinylcholine retains more than 90% of its original activity when stored at room temperature for 3 months; it retains even more if protected from light.73 Succinylcholine may be kept at room temperature in the ED or EMS setting, provided that a proper inventory control system ensures that all supplies are replaced not more than 3 months after introduction.

**Competitive Agents.** Competitive NMBAs are classified according to their chemical structure. The aminosteroid agents include pancuronium, vecuronium, and rocuronium. Vecuronium neither releases histamine nor exhibits cardiac muscarinic blockade and is an excellent agent for maintenance of neuromuscular blockade when this is desirable. Rocuronium is the best agent for use in RSI when succinylcholine is contraindicated.

of sedation and analgesia often obviates the need for an NMBA. Additional medication may be required if the patient’s blood pressure and heart rate indicate excessive sympathetic tone.

Induction Agents

A patient who presents with any degree of clinical responsiveness, including reactivity to noxious stimuli, requires a sedative or induction agent at the time of administration of any NMBA. Patients who already are deeply unconscious and unresponsive may not require a full dose of an induction agent if the unconscious state is caused by drugs or alcohol themselves general anesthetic agents. Patients who are unconscious because of a central nervous system insult should receive an induction agent to attenuate adverse responses to airway manipulation. Induction agents also enhance the effect of the NMBA and improve intubation conditions because the intubation is done at the earliest phase of neuromuscular blockade, and the relaxation effects of the induction agent are additive to those of the NMBA.75

Etomidate. Etomidate is an imidazole derivative that has been in use since 1972. Its activity profile is similar to that for thiopental, with rapid onset, rapid peak activity, and brief duration, but it is remarkably hemodynamically stable.7,72 Etomidate has emerged as the agent of choice for ED RSI, and numerous reports attest to its effectiveness and safety.1,14 The induction dose is 0.3 mg/kg IV. Because etomidate is able to decrease ICP, cerebral blood flow, and cerebral metabolic rate without adversely affecting systemic mean arterial blood pressure and cerebral perfusion pressure, it is an excellent induction agent for patients with elevated ICP, even in cases of hemodynamic instability.77 Etomidate may cause brief myoclonus, but this is of no clinical significance. Etomidate by continuous infusion has been reported to cause suppression of endogenous cortisol production. Recently, controversy has emerged regarding the role of etomidate for intubation of patients with septic shock.79,81 Several retrospective studies have claimed to demonstrate that etomidate, used in a single dose for intubation, causes suppression of the adrenal response to exogenously administered adrenocorticotropic hormone, and have attempted to link this to increased mortality.82,83 Other retrospective studies have shown the opposite.84,85 Ironically, much of the original criticism of etomidate arose from the belief that adrenocortical response to exogenous corticotropin predicts outcome in patients with septic shock, a belief that has since been abandoned.86 Also, the most recent and comprehensive study of the role of corticosteroids in septic shock failed to show any benefit, casting further doubt about any possible mortality effect of a single dose of etomidate.87 Pending a properly constructed, prospective, randomized clinical trial, there is not sufficient evidence to support a recommendation that etomidate not be used in patients with septic shock.91,92 In fact, etomidate’s superior hemodynamic profile makes it an excellent choice in these generally unstable patients.

Barbiturates. Although both the thiobarbiturate, sodium thiopental, and the methylated oxybarbiturate, methohexital, have been used as induction agents for RSI, thiopental has been used more widely. The use of these agents has declined significantly, however, with the adoption of newer agents, particularly etomidate and propofol. The rapidly acting barbiturates are highly lipid-soluble and readily cross the blood-brain barrier, acting on the γ-aminobutyric acid receptor neuroinhibitory complex to rapidly depress central nervous system activity. A single dose of 3 mg/kg of thiopental produces loss of consciousness in less than 30 seconds, has a peak effect at 1 minute, and has a clinical duration of 5 to 8 minutes. Methohexital may have a slightly shorter duration of action but is more prone to cause central nervous system excitatory side effects, such as myoclonus. Thiopental is a negative inotrope and a potent venodilator and should be used with caution in patients whose cardiovascular reserve is diminished. For the same reason, thiopental should be avoided in a hypotensive patient who would not tolerate further compromise of circulation. Thiopental can release histamine and probably should not be used in asthmatic patients.

Benzodiazepines. Of the benzodiazepines, only midazolam is suited to use as an induction agent, with a normal induction dose of 0.2 to 0.3 mg/kg IV.77 In a dose of 0.3 mg/kg IV, midazolam produces loss of consciousness in about 30 seconds and has a clinical duration of 15 to 20 minutes.99 Midazolam is a negative inotrope comparable to thiopental and should be used with caution in hemodynamically compromised and elderly patients, for whom the dose can be reduced to 0.1 mg/kg or 0.05 mg/kg. Onset is slower at these reduced doses. Much lower doses than indicated are often used in ED intubations, perhaps because practitioners are familiar with the sedation doses, but not the anesthetic induction doses, of midazolam.90 These inadequate doses reduce the effectiveness of laryngoscopy, do not provide optimal blunting of adverse physiologic effects of laryngoscopy and intubation, and may compromise the patient’s amnesia for the intubation. Midazolam may be cerebroprotective, but less so than etomidate or thiopental.

Ketamine. Ketamine, a phencyclidine derivative, has been widely used as a general anesthetic agent since 1970. Ketamine is a reasonable choice for induction.77 Ketamine induces loss of consciousness in less than 30 seconds, has a peak effect at 1 minute, and has a clinical duration of 5 to 8 minutes. Methohexital may have a slightly shorter duration of action but is more prone to cause central nervous system excitatory side effects, such as myoclonus. Thiopental is a negative inotrope and a potent venodilator and should be used with caution in patients whose cardiovascular reserve is diminished. For the same reason, thiopental should be avoided in a hypotensive patient who would not tolerate further compromise of circulation. Thiopental can release histamine and probably should not be used in asthmatic patients.

Controversy exists regarding the use of ketamine in patients with elevated ICP because ketamine has been believed to increase cerebral metabolic rate, ICP, and cerebral blood flow.91 The evidence that ketamine can produce harm in this way is conflicting, however, and its role as an induction agent in trauma is significant because of its superior hemodynamic stability.92 Because of its tendency to release catecholamines and increase blood pressure, ketamine should probably be avoided in head trauma patients with normal or elevated blood pressure. However, in the hypotensive head trauma patient, ketamine is a reasonable choice for induction.77 Ketamine tends to produce unpleasant emergence phenomena, especially disturbing or frightening dreams in the first 3 hours after awakening. These reactions, which are more prominent in
adults than in children, in women than in men, in patients receiving larger doses, and in certain personality types, are mitigated by benzodiazepine administration. Patients (e.g., with asthma) who undergo RSI with ketamine should receive a sufficient dose of a benzodiazepine (e.g., 0.05 mg/kg of lorazepam) as part of postintubation management.

**Special Clinical Circumstances**

**Status Asthmaticus**

Status asthmaticus with supervening respiratory failure is a preterminal event. Respiratory failure in the asthmatic patient is not caused primarily by progressive worsening of the bronchospasm, but rather by eventual exhaustion and fatigue secondary to the effort of breathing against severe airway resistance. All patients who are intubated for status asthmatics are heavily sedated and receive mechanical ventilation. RSI permits the most rapid attainment of intubation, protects against aspiration, and induces the unconsciousness and motor paralysis necessary for optimal initiation of mechanical ventilation; it is the recommended technique for intubation of a patient in status asthmaticus. Difficult airway considerations are complex in an asthmatic patient because of impending respiratory arrest and the patient’s inability to tolerate attempts at awake intubation. Even when a difficult airway is identified in an asthmatic patient, RSI is usually the intubation method of choice, with a double setup for rescue cricothyrotomy when indicated. The asthmatic patient has highly reactive airways, and steps should be taken to minimize any additional bronchospasm that may occur during intubation. Lidocaine has been shown to suppress the coughing that occurs in response to airway manipulation and may improve ETT tolerance and reduce reactive bronchospasm in asthmatic patients. The balance of evidence suggests that lidocaine (1.5 mg/kg) is indicated as a pretreatment drug before intubation in status asthmatics and in asthmatic patients being intubated for reasons other than their asthma. High-dose, inhaled beta-agonists may provide maximal protection against reactive bronchospasm during intubation in asthmatics without active bronchospasm, and lidocaine may provide little additional benefit in this setting. This approach has not been tested in patients in status asthmatics, however. Ketamine has been shown to produce bronchodilation in humans and animal models and may be the ideal induction agent in asthma. Although reports to date have been limited, there is a growing body of experience with ketamine as an induction agent for the emergency intubation of patients with status asthmaticus. Ketamine also has been reported to mitigate bronchospasm in patients who are not intubated and in patients who are already intubated and who are not improving with mechanical ventilation (Table 1-4).

**Hemodynamic Consequences of Intubation**

Laryngoscopy and intubation are potent stimuli for the reflex release of catecholamines. This reflex sympathetic response to laryngoscopy (RSRL) produces only modest increases in blood pressure and heart rate and is of little consequence in otherwise healthy patients. The RSRL is of potential clinical significance in two settings: acute elevation of ICP and certain cardiovascular diseases (e.g., intracerebral hemorrhage, subarachnoid hemorrhage, aortic dissection or aneurysm, and ischemic heart disease). In these settings, the reflex release of catecholamines, increased myocardial oxygen demand, and attendant rise in mean arterial blood pressure and heart rate may produce deleterious effects. The synthetic opioids (e.g., fentanyl) and beta-adrenergic blocking agents (e.g., esmolol) are capable of blunting the RSRL and stabilizing heart rate and blood pressure during intubation. Lidocaine also has been studied, but the results are contradictory and inconclusive. In patients at risk from acute blood pressure elevation, administration of fentanyl (3 µg/kg) during the pretreatment phase of RSI attenuates the heart rate and blood pressure increase. The full sympatholytic dose of fentanyl is 5 to 9 µg/kg, but if this dose is administered as a single pretreatment bolus, hypoventilation or apnea can occur. The administration of 3 µg/kg is safer and can be supplemented with an additional 3 µg/kg immediately after intubation if full sympathetic blockade is desired or if hypertension and tachycardia ensue, providing evidence of excessive sympathetic activity. Fentanyl should be given as the last pretreatment drug over 60 seconds to prevent hypoventilation or apnea.

**Elevated Intracranial Pressure**

When ICP is elevated as a result of head injury or acute intracranial catastrophe, maintenance of cerebral perfusion pressure and avoidance of further increases in ICP are desirable. Significant reductions in mean arterial blood pressure decrease cerebral perfusion pressure by reducing the driving gradient between arterial pressure and ICP, leading to increased cerebral ischemia. Maintenance of the systemic mean arterial blood pressure at 100 mm Hg or greater supports the cerebral perfusion pressure and reduces the likelihood of secondary injury. In addition, cerebral autoregulation may be lost, and increases in systemic blood pressure may lead to corresponding increases in cerebral blood flow and ICP. With elevated ICP, control of the reflex hemodynamic stimulation resulting from intubation is desirable to avoid further elevation of ICP. Fentanyl (3 µg/kg) given as a pretreatment drug is the best choice for this purpose in the emergency setting.

Evidence suggests a separate reflex that increases ICP in response to laryngoscopy and intubation, although the precise mechanism is not understood. IV lidocaine reduces ICP and

blunts the ICP response to laryngoscopy and intubation. Lidocaine (1.5 mg/kg IV), administered during the pretreatment phase of RSI, is desirable to blunt the ICP response to laryngoscopy and intubation. Similarly, RSRL and ICP response to laryngoscopy and intubation relatively contraindicate BNTI, which should be undertaken only if RSI is impossible and fiberoptic intubation is not an option.

The physician should choose an induction agent that balances a favorable effect on cerebral dynamics and ICP with a stable systemic hemodynamic profile. At present, etomidate (0.3 mg/kg) probably is the best choice for patients with elevated ICP, although thiopental also is an excellent choice when hypotension is not present (Table 1-5).

### Potential Cervical Spine Injury

Historically, it was believed that oral endotracheal intubation carried an unacceptably high risk of injury to the cervical spinal cord in patients with blunt cervical spine injury and was relatively contraindicated, but this assertion was never subjected to scientific scrutiny. Numerous studies and reports have asserted the safety and effectiveness of controlled, oral intubation with in-line cervical spine immobilization, whether done as an awake procedure or with neuromuscular blockade. The evidence favors RSI with in-line stabilization, which provides maximal control of the patient, the ability to mitigate adverse effects of the intubation, and the best conditions for laryngoscopy. In-line stabilization also seems to improve the laryngoscopic view of the larynx compared with conventional tape/collar/sandbag immobilization. The intubating laryngeal mask airway (ILMA) also has been compared with conventional laryngoscopy and may result in less movement of the cervical spine during intubation than that caused by direct laryngoscopy. A comparison of methods on a cadaver model of unstable injury of the third cervical vertebra reinforced the potential role for fiberoptic intubation and raised questions about the safety of the Combitube because of significant cervical spine movement during its placement. Newer devices have also shown promise for safe intubation of patients with cervical spine injury. A fluoroscopic study comparing intubation using the Shikani optical stylet (SOS) to that done with direct laryngoscopy showed significantly less cervical spinal movement with the SOS, but a slightly longer time (28 sec vs. 17 sec) to achieve intubation. The Airtraq, a single-use intubation device, resulted in better glottic views and more rapid intubation of patients with cervical spine immobilization than direct laryngoscopy using a Macintosh blade. The Glidescope, a video laryngoscope, provides superior glottic views with reduced or comparable cervical spine movement when compared with conventional direct laryngoscopy using the Macintosh blade.

Cervical spine immobilization of patients with penetrating head and neck trauma is poorly addressed in the literature. It is not proven whether patients with gunshot or shotgun injuries to the head or neck are at risk of exacerbation of cervical cord injury during intubation, but there is no report of such a patient, with or without clinical evidence of spinal cord injury, who was injured by intubation. If the path of the missile is felt not to involve the bony spinal column and there is no evidence of spinal cord injury, prudence would dictate immobilization of patients with gunshot wounds to the head or neck with a secondary injury mechanism (e.g., fall from height) or with neurologic deficit suggesting spinal involvement. Immobilization for intubation of patients with penetrating injury elsewhere in the body should be directed by the likelihood of secondary injury to the spine from a fall or other event distinct from the wounding.

### Pediatric Intubation

Although many considerations in pediatric intubation are the same as for adults, a few differences exist in regard to airway management. The larynx is higher in the child's neck, causing a more acute angle between the oral pharynx and the larynx. Visualization is aided by gentle posterior pressure on the anterior aspect of the thyroid cartilage. The epiglottis is high and soft, making visualization of the cords more difficult. If the child is very small, the prominent occiput brings the mouth to a position far anterior to the larynx; an assistant can lift the chest gently by grasping both shoulders, immobilizing the head at the same time. The airway in the small child is short, and care must be taken not to intubate either bronchus.

A straight laryngoscope blade is desirable to displace the floppy epiglottis, especially in young children, and positioning for intubation may be different. BNTI is relatively contraindicated in children younger than 12 years old. Although the product insert for succinylcholine now advises against its routine use in pediatric anesthesia because of the risk of hyperkalemia in children with undiagnosed congenital neuromuscular disorders (e.g., muscular dystrophy), it remains the drug of choice for emergency RSI of infants and children. Rocuronium has been used in children, but experience is too limited to recommend that it replace succinylcholine for pediatric RSI in the ED. RSI may be used in children in a similar manner to adults, with two important differences. Excessive bradycardia may be seen with succinylcholine in children younger than 1 year old, but it is not known whether administration of atropine (0.02 mg/kg) during the pretreatment phase prevents any possible adverse outcome. The dose of succinylcholine in infants is 2 mg/kg. Induction agents may be selected using similar criteria as for adults. The major difficulty in intubating children and infants is choosing the correct size of equipment and the correct drug doses for age or size. These obstacles can be overcome by use of a length-based system (Broselow-Luten Color Coding Kids; Vital Signs, Inc., Totowa, NJ), which provides dosing and equipment sizes based on the length of the child. Cricothyrotomy is impossible.
in small children, and alternative rescue airway devices (e.g., percutaneous oxygenation via the cricothyroid membrane) are required.

Other Airway Devices and Techniques

Regardless of the care taken by the intubator and the detailed assessment of the patient before intubation, some intubations are simply unsuccessful or impossible. In most circumstances when intubation is not possible, BMV or ventilation using an EGD provides adequate ventilation and oxygenation until a rescue airway can be established. This underscores the importance of evaluating the patient for ease of intubation, ventilation, and EGD use before deciding on the best approach and initiating the intubation sequence. Over the past 10 years, there has been a revolution in airway management, based primarily on the incorporation of video and fiberoptic technology into laryngoscopes and stylets. In addition, increasing experience with extraglottic devices and other approaches has proved useful both for routine and difficult or failed airways.

Extraglottic Devices

Laryngeal Mask Airway. The laryngeal mask airway (LMA) is an irregular, ovoid, silicone mask with an inflatable rim, connected to a tube that allows ventilation (Fig. 1-10). It is available in both reusable and single-use configurations; single-use models are offered by several manufacturers and are probably equivalent. The mask is inserted blindly into the pharynx, then inflated, providing a seal that permits ventilation of the trachea with minimal gastric insufflation. In elective anesthesia, the LMA has an extremely high insertion success rate and low complication rate, including a low incidence of tracheal aspiration.105,106 In the emergency setting, studies to date have focused on use during resuscitation from cardiopulmonary arrest, although data are beginning to emerge for use of the LMA as a rescue device in the event of failed intubation and as an alternative to direct laryngoscopy for intubation or a bag-valve-mask for ventilation.107 Evaluations of LMA insertion by experienced and inexperienced personnel consistently have shown ease of insertion, high insertion success rates, and successful ventilation.108 Novice users appear to be able to both ventilate and intubate more easily and successfully with the intubating LMA (ILMA) than by bag-mask ventilation and direct laryngoscopy.109 The LMA may be a viable alternative to endotracheal intubation for in-hospital or out-of-hospital treatment of cardiac arrest, particularly when responders are inexperienced airway managers. At a minimum, the device may serve a temporizing role equal or superior to BMV until definitive airway management can be achieved. A new form of LMA, the iGel, has a viscous gel within the cuff, so does not require inflation. Initial experience with the device, even with minimally trained novice users, is promising, with high insertion success rates and short insertion times.109

The ILMA is designed to facilitate intubation through the mask after correct placement (Fig. 1-11). It differs from the LMA in two main ways: The mask is attached to a rigid, stainless steel ventilation tube that is bent almost to a right angle, and the mask incorporates an epiglottic elevator at its distal end. Placement of the ILMA results in successful ventilation in almost 100% of cases and successful subsequent intubation in 95%.97,110-112 The ILMA can also be used for both ventilation and intubation in obese patients with similarly high success rates.113 The ILMA has a special ETT and a stabilizer rod to remove the mask over the ETT after intubation is accomplished, but intubation can be comparably successful with a conventional polyvinylchloride (PVC) endotracheal tube.114

The ILMA is a better device than the standard LMA for use in the ED because it facilitates both rescue ventilation and intubation. Intubation through the ILMA has compared favorably in terms of success with direct laryngoscopy and is superior in the hands of relatively novice intubators.106,110 When the ILMA is placed, intubation can be performed blindly or guided by a lighted stylet or a fiberoptic scope. The ILMA comes only in sizes 3, 4, and 5 and so is not suitable for use in patients weighing less than about 30 kg. For smaller patients, the standard LMA, which has sizes down to size 1 (infant), should be used. Intubation can be achieved through the standard LMA.

Figure 1-10. The standard laryngeal mask airway (LMA Classic) is available in sizes from infant to large adult. (Courtesy LMA North America, Inc., San Diego.)

Figure 1-11. The intubating laryngeal mask airway is modified to facilitate insertion of an endotracheal tube after placement and ventilation are achieved. The epiglottic elevator (triangle) lifts the epiglottis to allow passage of the special ETT (arrow).
but the success rate is significantly less than with the ILMA. As experience with both the LMA and ILMA grows, it is likely that there will be increasing adoption of the LMA as a primary airway management technique by nonhospital first-responders, and the ILMA is gaining attention as a primary rescue device in the ED.

A new version of the ILMA, the CTrach incorporates fiberoptic bundles and a detachable viewing screen to provide a view of the glottis during intubation. The device performs better than the standard ILMA for first attempt intubation, where it achieves almost 95% success versus approximately 80% for the ILMA in one well-conducted study.115 Ultimately, though, the ILMA’s intubation success rate is so high (on three or fewer attempts) that it is not clear that the CTrach provides additional benefit overall. The view can uncommonly be obscured by secretions, but this is easily solved by removing and reinserting the device, or cleaning it with a swab through the airway lumen.116

In the ED, the primary use of the LMA or ILMA is as a rescue technique to provide a temporary airway when intubation has failed, bag ventilation is satisfactory, and the patient has been paralyzed or is otherwise in need of immediate airway management. In such cases, the LMA is one of numerous acceptable devices. In the “can’t intubate, can’t ventilate” situation, cricothyrotomy is indicated, but an ILMA may be placed rapidly in an attempt to achieve ventilation (converting the situation to “can’t intubate, can ventilate”) as long as this is done in parallel with preparations for cricothyrotomy and does not delay the initiation of a surgical airway.107 Availability of the LMA and adequate prior training of the clinician offer a legitimate option for the management of the failed airway, and the ILMA compares well with fiberoptic intubation in terms of successful intubation of difficult airways.115 The standard LMA may also offer advantages for providing ventilation in unconventional positions, such as when the patient is lying on his or her side.115 In the out-of-hospital setting, where concerns about esophageal placement of ETTs have focused interest on methods used for airway management, the LMA and Combitube offer excellent placement and ventilation characteristics and may be preferable to endotracheal intubation in this setting, especially when intubation is relatively infrequently performed.118 If the patient is in a difficult position in terms of intubation access, the LMA may facilitate more rapid ventilation.119 New LMA devices, from a number of manufacturers, are now available.

**Esophagotracheal Combitube.** The Combitube is a plastic double-lumen tube with one lumen functioning as an airway after esophageal insertion and the other lumen functioning as a tracheal airway (Fig. 1-12). The tube is placed blindly into the esophagus, and proximal and distal balloons are inflated to prevent escape of ventilatory gases through the pharynx to the mouth or nose or down the esophagus. The tube is placed into the esophagus, as designed, almost 100% of the time, but both lumens are patent, so ventilation is still possible if the tube has been placed inadvertently into the trachea.

The Combitube is primarily a substitute for endotracheal intubation for non-ETT-trained personnel, but it also has a role as a primary airway device in place of endotracheal intubation in the out-of-hospital setting.120 It has been used as a rescue device or as a primary intubating device in difficult airways that have precluded endotracheal intubation or successful LMA placement, both in patients with and those without cardiac arrest.121,122 Serious complications attributable to Combitube use are uncommon.123 The tube may be difficult to insert blindly when the patient is in cervical spine precautions, raising concerns about first-responder use in trauma patients, but results have been conflicting.124,125 Standard methods for confirming tube placement, using ETCo2, seem to be reliable in identifying whether the tube has been passed into the esophagus or trachea and in confirming the correct ventilation port.

Although the Combitube has provided successful ventilation for several hours, it should be considered a temporizing measure only. Current use in the ED should be restricted to rescue placement after failed oral intubation with adequate BMV or a quick maneuver in the “can’t intubate, can’t oxygenate” patient simultaneous with preparation for a cricothyrotomy (analogous to the use of the ILMA in this situation). The Combitube has virtually no role in the ED as a primary airway management device except in cases of cardiopulmonary arrest when expertise for endotracheal intubation is not available.

**Video Laryngoscopes**

New devices incorporate video imaging into modified laryngoscopes to allow superior visualization of the glottis without the need to create a straight-line visual axis through the mouth. The Glidescope uses an extended Macintosh blade with a sharply angulated tip to direct the video camera at the glottis, even in patients with difficult airways (Fig. 1-13). When compared with direct laryngoscopy, the Glidescope provides an equivalent or superior glottic view, and has a very high intubation success rate.126,127 The Glidescope appears to cause less cervical spine movement than conventional direct laryngoscopy with a Macintosh blade.101 The C-MAC video laryngoscope (Fig. 1-14) incorporates a complementary-metal-oxide-semiconductor (CMOS) video chip into otherwise conventional laryngoscope blades, to enhance glottic view. Other videolaryngoscopes are available or under development. Overall, videolaryngoscopy offers the promise of transforming laryngoscopy and has the potential to render conventional, direct laryngoscopy obsolete.128

**Fiberoptic Intubating Stylets**

Several rigid fiberoptic intubating stylets have also been approved and adopted into clinical use.129 The Shikani Optical Stylet (SOS—Clarus Medical, Minneapolis, Minn.) is the most studied of these. The endotracheal tube is placed over the
The GlideScope (Verathon, Inc.) is a video laryngoscope that uses a 50° deflection of the distal tip of the blade (which is otherwise similar to an extended MAC-3 blade) to direct the video camera and light source directly at the glottis without repositioning the head. The endotracheal tube insertion is done under direct vision via the video screen. (From Walls RM, Murphy MF [eds]: Manual of Emergency Airway Management, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, p. 171, 2008, with permission.)

The C-MAC video laryngoscopy (Karl Storz Endoscopy) uses an integrated CMOS video chip to capture a video image from near the distal tip of an otherwise conventional laryngoscope blade. The image is conveyed to a video screen where it is viewed by the intuber. (From Walls RM, Murphy MF [eds]: Manual of Emergency Airway Management, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, p. 173, 2008, with permission.)

The Shikani optical stylet (SOS, Clarius Optical) with endotracheal tube mounted. The eyepiece and battery pack are at the right.

The C-MAC video laryngoscopy (Karl Storz Endoscopy) uses an integrated CMOS video chip to capture a video image from near the distal tip of an otherwise conventional laryngoscope blade. The image is conveyed to a video screen where it is viewed by the intuber. (From Walls RM, Murphy MF [eds]: Manual of Emergency Airway Management, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, p. 173, 2008, with permission.)

The Bonfils intubating fiberscope (Karl Storz Endoscopy of America, Culver City, Calif.) functions as a retro-molar intubating stylet (Fig. 1-16). The ETT is loaded directly onto the nonmalleable fiberoptic stylet, then guided along the cheek and directed around posterior to the back molar, then through the glottic aperture by direct fiberoptic visualization.

Flexible Fiberoptic Scopes

Intubation using a flexible fiberoptic scope is increasingly applied to difficult airways in the ED, after many years of use for similar applications in the operating room. The intubating fiberoptic bronchoscope can be passed through the vocal cords under fiberoptic visualization, then can serve as an introducer over which the ETT is passed. Fiberoptic examination facilitates airway assessment for the need for intubation, without definitely committing the patient to intubation, as is the case when an NMBA is administered for RSI. For example, in a patient with smoke inhalation, examination with the fiberoptic scope might identify that intubation is not required, but will also facilitate intubation when it is indicated. Intubation of morbidly obese patients, those with distorted airway anatomy (e.g., penetrating or blunt anterior neck injury), or those with fixed cervical spine deformity, can be achieved using the fiberoptic scope, topical anesthesia, and moderate (procedural level) sedation, thus preserving the patient’s ability to breathe until intubation is achieved. The fiberoptic scope also has been used successfully in concert with the ILMA to achieve intubation in difficult cases, including when the cervical spine is immobilized, where it significantly outperforms conventional laryngoscopy.

There is a significant learning curve for flexible fiberoptic intubation, and fiberoptic examination of the upper airway in
patients with pharyngitis or odynophagia, for example, is helpful, as it requires the same “navigation skills” as are required for intubation. Use of a video attachment for instruction, so that the instructor and learner can simultaneously see the same image appears to enhance learning. Models have been created to allow learners to navigate through a series of openings and around barriers, which also increases subsequent intubation performance. The role of flexible fiberoptic intubation in the ED is greatly expanding, as obesity increases in the population, and, increasingly, difficult airways are handled in the ED without backup. The transition from fiberoptic to CMOS video technology should make these flexible scopes more prone, less prone to fogging, and less expensive—all desirable attributes for emergency intubation. Emergency physicians should have immediate access to fiberoptic scopes and should endeavor to acquire training and practice in their use. Fiberoptic scopes are of great value in the patient with predicted difficulty in direct laryngoscopy, EGD use, and BMV. The expanding use of video laryngoscopy will redefine the role of flexible fiberoptic scopes, as video laryngoscopy solves many of the difficulties that occur with direct laryngoscopy.

Other Intubation Techniques

Retrograde Intubation. In retrograde intubation, a flexible wire is passed in retrograde fashion through a cricothyroid membrane puncture. The wire is retrieved through the mouth, then used to facilitate intubation by serving as a guide over which the ETT is passed. Purported advantages of retrograde intubation include ease of learning and application to the difficult airway. Although retrograde intubation theoretically may be useful when the upper airway is disrupted by trauma, rendering oral intubation difficult or impossible, it is unlikely to be used in the ED except in circumstances in which alternative devices, such as fiberoptic intubation, Trachlight, Combitube, and cricothyrotomy, are unavailable. Published reports of its use in emergency circumstances have been limited to case reports, very small series, and review articles. It is doubtful whether retrograde intubation would ever be the airway maneuver of first choice in the ED, but it may be a useful consideration in rare, unique difficult airway cases.

Lighted Stylet. The lighted stylet is a device that incorporates a handle, a fitting for mounting an ETT, and an intubating stylet with a fiberoptic light mounted on the end (Fig. 1-17). The ETT is mounted as on a conventional intubating stylet, but transillumination of the soft tissues from within the neck permits identification of tracheal entry by the stylet and ETT. The lighted stylet has been used for oral and nasal intubation and has an excellent success rate. The lighted stylet is less stimulating to the heart rate and blood pressure than conventional laryngoscopy and may be useful when sympathetic stimulation is not desirable. Although overall success rates with the Trachlight lighted stylet have been high, it may be more difficult for novice intubators to learn than conventional laryngoscopy, if only minimal manikin training is used. The Trachlight can be used as a primary intubating device or as a rescue device in the “can’t intubate, can’t ventilate” failed airway. It is not appropriate for the “can’t intubate, can’t ventilate” failed airway, when cricothyrotomy is indicated. As a device for a difficult airway, the lighted stylet can be used as the intubating stylet for a standard oral intubation. The direct illumination by the stylet can aid in visualization during intubation. If direct laryngoscopy is unsuccessful, the first rescue procedure could be an immediate attempt at blind, oral intubation using the lighted stylet, as long as ventilation is possible. There is also some evidence that the Trachlight produces less cervical spine motion than does direct laryngoscopy.

Surgical Airway Management

Needle Cricothyotomy with Transtracheal Jet Ventilation

Needle cricothyotomy involves the insertion of a large needle (ideally 10-gauge) through the cricothyroid membrane into the airway. When inserted, the needle is used to ventilate the patient with a standard wall oxygen source. Because of the high-velocity ventilation that ensues through the narrow catheter, this procedure is called transtracheal jet ventilation. Transtracheal jet ventilation has been used successfully in humans and has been subjected to various animal experiments to determine its uses and limitations. It rarely has been used in patients in EDs, however, where its role as a rescue device in the “can’t intubate, can’t ventilate” situation is vastly inferior to cricothyrotomy.

The jet ventilator should include a regulator and gauge so that pressures can be monitored and reduced, especially in children (Fig. 1-18). Upper airway obstruction has been considered a contraindication to transtracheal jet ventilation, but ventilation still can be successful, although at the cost of higher intrapleural pressure and possibly pulmonary barotrauma. In general, when upper airway obstruction is present in adults, percutaneous or surgical cricothyrotomy is preferred.

The primary indication for transtracheal ventilation in the ED is the initiation of emergency oxygenation for a pediatric patient who is apneic (either because of the presenting condition or because of administration of an NMBA) and in whom intubation and BMV are impossible. Cricothyrotomy is extremely difficult or impossible in children younger than 10 years old, and transtracheal ventilation should be considered the surgical rescue modality of choice in this age group. For children younger than 5 years old, bag ventilation is used with the percutaneous catheter, and pressurized devices are avoided.

Cricothyrotomy

Cricothyrotomy is the creation of an opening in the cricothyroid membrane through which a cannula, usually a cuffed tracheostomy tube, is inserted to permit ventilation. The techniques, and variations thereof, are well described elsewhere. When surgical airway management is required, cricothyrotomy is the procedure of choice in the emergency setting, where it is faster, more straightforward, and more likely to be successful than tracheotomy.

Cricothyrotomy is indicated when oral or nasal intubation is impossible or fails and when BMV cannot maintain adequate oxygen saturation (the “can’t intubate, can’t ventilate” situation). Several large series have established that the incidence of cricothyrotomy is approximately 1% of all ED intubations.
PART I
Fundamental Clinical Concepts
Section One
Critical Management Principles

Cricothyrotomy is relatively contraindicated by distorted neck anatomy, preexisting infection, and coagulopathy; these contraindications are relative, however, and the establishment of the airway takes precedence over all other considerations. Successful cricothyrotomy after systemic fibrinolytic therapy has been reported. The procedure should be avoided in children younger than 10 years old, in whom anatomic considerations make it exceedingly difficult. Studies suggest that approximately five “practice” cricothyrotomies on a simulator or animal model are sufficient to achieve at least baseline capability with the procedure.

Cricothyrotomes are devices used to perform percutaneous cricothyroidotomy. Percutaneous cricothyrotomy using the Seldinger technique appears comparable to formal open cricothyrotomy in terms of ease of learning and success rates. The safety and effectiveness of other cricothyrotomes are not clearly established. A recently released kit by Portex offers a small red flag indicator to warn when the posterior tracheal wall is touched, but a cadaver study showed that, although the device resulted in somewhat faster placement of an airway than did a Seldinger technique, the incidences of both failure and major complications (posterior airway wall laceration) were unacceptably high, so the device cannot be recommended. Only two percutaneous cricothyrotomy sets on the market currently have the ability to place a cuffed tracheostomy tube. One is a dedicated Seldinger cricothyrotomy set; the other is a combination set that has all necessary equipment for either a Seldinger percutaneous cricothyrotomy or a standard surgical cricothyrotomy (Melker universal cricothyrotomy kit; Cook Critical Care, Bloomington, Ind.) (Fig. 1-19).

OUTCOMES

Few studies of emergency airway management have characterized complications and outcomes. The largest single-institution series reported a success rate for ED RSI of 99% and a complication rate of 9.5%; most complications were minor. Phase II of the large National Emergency Airway Registry Study (NEAR II) of almost 9000 ED intubations reported success rates of approximately 97% for RSI. The NEAR classification system characterizes potentially adverse occurrences during intubation as “adverse events.” In the NEAR study, the observed rate of adverse events was approximately 9% in medical patients and 8% in trauma patients, and most of these were minor. No studies have evaluated the long-term outcome of intubated ED patients.

Figure 1-18. Transtracheal jet ventilation. High-pressure ventilation tubing (black triangle) attaches to standard wall oxygen outlet at 55 psi. Ventilation block (middle white triangle) is used to control oxygen flow through tubing (top left white triangle) to catheter (lower right triangle), which is inserted in the airway.

KEY CONCEPTS

Knowledge of the clinical course of the patient’s condition and anticipation of possible deterioration are crucial to the decision to intubate, especially if the patient is to leave the ED for a time (e.g., interfacility transfer, diagnostic testing).

Assessment of the patient for potential difficulty with intubation, bag-mask ventilation (BMV), ventilation using an extraglottic device (EGD), and cricothyrotomy is an essential step in planning airway management. The mnemonics LEMON, MOANS, and RODS can serve as useful aids.

In the absence of a “crash” patient (agonal, unresponsive to laryngoscopy) or a difficult airway, RSI is the airway management method of choice for ED patients.

Succinylcholine is the NMBA of choice for ED RSI, but it should be avoided in certain patient groups because of risk of significant hyperkalemia.

Pretreatment drugs given during RSI can mitigate adverse responses to intubation and improve the patient’s clinical condition.

Tube placement confirmation using end-tidal CO₂ (ETCO₂) is essential after intubation, and failure to detect adequate quantities of exhaled CO₂ is evidence of esophageal intubation until proven otherwise.

Videolaryngoscopy is transforming intubation by eliminating the traditional anatomic barriers to direct laryngoscopy. Emergency practitioners should evaluate video laryngoscopes for incorporation into their practice, both for difficult and routine intubations.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Invasive and noninvasive ventilation are essential tools for treatment of critically ill patients. The indications for endotracheal intubation (ETT) and for assisted ventilation in the emergency department (ED) are not always the same. Some patients require support for respiratory failure or as part of comprehensive management of critical illness, while others’ cardiopulmonary function may be preserved and assistance is needed primarily for airway protection.

The decision to intubate is discussed in Chapter 1 and in various other places throughout this textbook in the context of individual conditions. This chapter describes the modalities and techniques of mechanical ventilation.

### PERSPECTIVE

In volume-cycled ventilation, inhalation ends when a preset tidal volume has been delivered, and inspiratory pressure varies with the inverse of lung compliance. The benefit to this method is the ability to control tidal volume; the risk is potentially high peak pressures when compliance is poor. There is no consensus regarding which approach to positive-pressure ventilation is better; pressure- and volume-cycling are opposite sides of the same coin, and both strategies are used clinically.

The most commonly available modes of positive-pressure ventilation are (1) controlled mechanical ventilation (CMV), (2) assist/control (A/C) ventilation, and (3) synchronized intermittent mandatory ventilation (SIMV), all of which can be supplied through either pressure-cycled or volume-cycled ventilators. Two main factors differentiate these modes from one another: (1) how a breath is triggered (at a preset fixed rate or by a patient’s inspiratory effort sensed by the ventilator), and (2) the target capacity (pressure or volume) for each breath.

During CMV, the ventilator delivers breaths at a preset rate, regardless of any ventilatory effort made by the patient. A person receiving CMV can neither trigger a breath nor inspire gas spontaneously through the ventilator circuit, so this mode is appropriate only for apneic, pharmacologically paralyzed, and deeply sedated patients. In contrast, a ventilator applying A/C mode continuously monitors the ventilator circuit for spontaneous breathing (i.e., the delivery of a mechanical breath before the previous breath has been completely exhaled). Stacking may result in hyperinflation and barotrauma. If spontaneous breathing occurs at a rate equal to or lower than the preset ventilator rate,
the patient’s inspiration, or an elapsed time, triggers the next breath delivery. If the patient’s spontaneous breathing is faster than the established SIMV rate, the patient breathes gas from the ventilator circuit and receives a volume consistent with his or her inspiratory effort, in addition to regular breaths at the set tidal volume and rate, which are triggered by the patient and delivered by the ventilator.

Regardless of the ventilatory mode chosen, additional refinements are available and commonly used. The most important of them is positive end-expiratory pressure, or PEEP. PEEP and continuous positive airway pressure (CPAP), a closely related entity, refer to the maintenance of positive airway pressure after the completion of passive exhalation. By convention, PEEP refers to pressure applied during invasive mechanical ventilation, whereas CPAP is the application of positive pressure (invasively or noninvasively) during spontaneous breathing. The terms are occasionally used interchangeably. Acute lung injury and cardiogenic pulmonary edema are characterized by loss of surfactant function. The chief beneficial effect of PEEP or CPAP is to increase functional residual capacity (FRC) by maintaining patency of injured or flooded alveoli that would otherwise collapse at the end of exhalation. Increasing the FRC may improve both oxygenation and lung compliance. One of the potential adverse effects of PEEP is decreased cardiac output.

Pressure support ventilation (PSV) is another adjunct in which breathing is controlled by the patient, and peak pressures are controlled by the ventilator. The primary goal of PSV is to support the patient’s spontaneous breathing effort while providing satisfactory oxygenation. PSV provides for the prompt attainment of a preset PIP each time the patient initiates inspiratory effort. Inspiratory time, inspiratory flow rate, and tidal volume (TV) are augmented, whereas inspiratory work of breathing is reduced. The machine likewise senses and tidal volume (TV) are augmented, whereas inspiratory work of breathing is reduced. The machine likewise senses and responds to the patient’s respiratory efforts. EPAP splints airways open and prevents alveolar collapse and atelectasis. IPAP decreases and prevents alveolar collapse and atelectasis. IPAP decreases the work of breathing and improves TV (Fig. 2-1).

**Noninvasive Techniques**

Noninvasive positive-pressure ventilation (NPPV) includes CPAP or biphasic positive airway pressure (BiPAP) and is applied with a face or nose mask. CPAP provides constant pressure throughout the respiratory cycle, and its benefits were discussed earlier in relation to PEEP. BiPAP alternates between higher pressure during inspiration (IPAP) and lower pressure during expiration (EPAP). The machine senses and responds to the patient’s respiratory efforts. EPAP splints airways open and prevents alveolar collapse and atelectasis. IPAP decreases the work of breathing and improves TV (Fig. 2-1).

**Invasive versus Noninvasive Approach**

Alert patients with a patent airway and an intact respiratory drive, even if that drive is insufficient, may be candidates for NPPV. Patients most likely to respond to NPPV in the ED are those with more readily reversible causes of their distress, such as COPD exacerbation or cardiogenic pulmonary edema, in which fatigue is a significant factor. Patient selection, comprehensive management of the underlying condition, and ongoing monitoring are essential for successful NPPV. NPPV

---

*Figure 2-1. Pressure, flow, and waveforms typically encountered during mechanical ventilation in the emergency department. The nature of fresh gas delivery during mechanical ventilation is in part a function of the definition of “breath” (i.e., a delivered volume or delivered pressure) and the means by which that breath is initiated (i.e., by the patient or by a timing decision made by the ventilator). In practice, only a handful of ventilator parameters commonly are managed in the emergency department (the mode, the magnitude of the delivered breath, the rate of delivery, and FIO₂). However, as this figure shows, a number of additional features can be fine-tuned to optimize the effectiveness and comfort of mechanical ventilation in critically ill patients. (Modified from Mason RJ: Murray and Nadel's Textbook of Respiratory Medicine, 4th ed. Philadelphia: Elsevier, 2005.)*
has been shown to be a beneficial initial intervention for both congestive heart failure (CHF) and COPD. Although studies have significant flaws, they have consistently demonstrated reduced need for intubations in both conditions, as well as a mortality benefit in COPD patients. In COPD, NPPV decreases the work of breathing and splints airways open, increasing ventilation-perfusion matching. Predictors for success in COPD include younger age, unimpaired consciousness, less severe acidemia, and prompt response (less than 2 hours), as measured by heart rate, respiratory rate, and gas exchange. Predictors for failure in COPD include a Glasgow Coma Score less than 11, an arterial pH less than 7.25, and tachypnea greater than 30 breaths per minute. In CHF, NPPV reduces work of breathing, improves cardiac output by decreasing preload and afterload, redistributes lung water, and improves ventilation-perfusion matching thereby reducing shunt. However, although symptoms during acute exacerbations of CHF are improved, a mortality benefit has not been detected. Some trials have used NPPV for hypoxemic respiratory failure such as in pneumonia; however, the results are not clearly beneficial.

Contraindications to NPPV include severely impaired level of consciousness, cardiac arrest, acute MI, inability to protect airway, apnea, copious secretions, uncontrolled vomiting, upper airway obstruction and facial trauma.

Patients in whom NPPV is initially chosen should be reassessed frequently for progress of therapy, tolerance of the mode of support, and any signs of clinical deterioration that indicate a need for intubation. NPPV is an attractive alternative to ETT because it reduces the risks of airway trauma and ventilator-acquired pneumonia and may be helpful in patients who decline intubation. NPPV also may be considered for a patient whose advanced directives proscribe intubation. An individualized approach is important, and discussion with the patient and family members may be helpful.

**Initial Settings and Ongoing Monitoring**

Recommended initial settings for BiPAP ventilators are an IPAP of 8 cm H2O and an EPAP of 3 cm H2O. Either a face mask or a nose mask can be used. The flow of supplemental oxygen bled into the circuit should be governed by pulse oximetry, as corroborated by arterial blood gas (ABG) results; it is appropriate to initiate therapy with 3 to 5 L/min of supplemental oxygen, but this should be adjusted with each titration of IPAP or EPAP. The ventilator should be in spontaneous mode to support the patient’s respiratory effort.

As the patient’s response to NPPV and other therapy is monitored (using cardiac and blood pressure monitors, ABGs, and oximetry, and the patient’s own voiced assessment of tolerance and progress), support pressures are adjusted. Although this adjustment must be individualized, a reasonable approach for BiPAP support in hypoxic patients is to increase EPAP in 2-cm H2O increments, with IPAP maintained at a fixed interval higher. Hypercapnia can be managed by increasing IPAP in 2-cm H2O increments, with EPAP being increased in approximately a 1:2.5 ratio to IPAP.

For the intubated patients, initial ventilator settings depend on the goal of the ventilatory intervention (mechanical ventilation, assisted ventilation, or PSV) and on the underlying cause of respiratory insufficiency. The basic parameters to be set in volume-cycled ventilators in CMV, A/C, IMV, and SIMV modes are fraction of inspired oxygen (FiO2), TV, rate, and inspiratory/expiratory (I/E) ratio. (The I/E ratio reflects the duration of machine insufflation and the rest periods between them.) If atelectasis is a problem, PEEP should be added; the addition of PEEP may permit the use of more physiologic FiO2 values as well. For an apneic or paralyzed patient, CMV, A/C, or IMV mode may be used. For a breathing patient with inadequate ventilatory effort, A/C is usually the best initial approach.

Reasonable initial ventilator settings are a TV of 6 to 8 mL/kg body mass and a rate of 12 to 14 breaths/min. Initial FiO2 should be set at 1.0 but generally can be adjusted down quickly to maintain an oxygen saturation of 90% or greater. Ventilator settings are adjusted dynamically using pulse oximetry, end-tidal carbon dioxide monitoring, ventilation pressures, clinical status, and ABGs as a guide. PEEP, if indicated, should be initiated at 2.5 to 5 cm H2O.

In pressure-cycled ventilators, the rate and FiO2 are set as described earlier. An inspiratory pressure should be chosen that results in a TV of 6 to 8 mL/kg, usually 25 to 40 cm H2O. There are additional specific considerations for many particular conditions (see section on Special Clinical Circumstances).

Mechanical ventilation is a dynamic process that requires constant monitoring and regular adjustment of these parameters. Tachycardia and hypertension can indicate ventilator intolerance and a need for increased sedation or adjustment of the ventilator settings. Bradycardia and ventricular irritability represent hypoxemia until this is disproved. Unless capnometry and pulse oximetry are in use, an ABG should be measured approximately 20 minutes after initiating support. These results indicate the sufficiency of ventilation (using the pH and arterial partial pressure of carbon dioxide, PaCO2) and oxygenation (using arterial oxygen partial pressure, PaO2). Adjustments in minute volume (the product of TV and rate) and FiO2 can be guided by baseline measurements supplemented by ongoing monitoring. To avoid oxygen toxicity, FiO2 should be reduced to the lowest level that provides acceptable (≥90%) oxygen saturation. In many instances PEEP will allow better oxygenation for a given FiO2.

Important ventilator readouts include the PIP and expiratory volume. PIP is among the most frequently referenced measures of ventilatory function during mechanical ventilation. It reflects lung compliance and airway resistance; changes in the magnitude of PIP may reflect any of several potentially detrimental problems related to ventilation. In a practical sense, PIP can be considered an additional vital sign for patients on a ventilator. Acute decreases in PIP reflect inadequate volume delivery to the patient, which may be caused by insufficient gas supply to the ventilator, inadvertent change in settings, a leak in the breathing circuit, unintended extubation, or failure of the ventilator. Increases in PIP may indicate ETT occlusion by secretions in or kinking of the tube, acute bronchospasm, pneumothorax, or conditions causing decreased lung compliance such as the development of worsening pulmonary edema. PIP can serve as a useful measure of effectiveness of therapy in patients with asthma or COPD; as airway resistance lessens, the PIP decreases. High PIP may cause barotrauma and other acute lung injury.

Measurement of expiratory volume and expiratory flow allows estimation of the effectiveness of spontaneous respiratory efforts and, by comparing expiratory volume with the set TV, assessment of the effectiveness of ventilation and the integrity of the breathing circuit. The expiratory volume measurement is particularly important in assessing mechanical ventilation in children, who often have air leaks around an uncuffed ETT.

**Patient Treatment**

Even if a mechanically ventilated patient’s stay in the ED is brief, attention must be paid to ventilatory management. Routine concerns are sedation, neuromuscular paralysis if
necessary, analgesia, and suctioning. Sedation and analgesia should be titrated to provide the greatest patient comfort and ventilation performance. In addition, a rapid and systematic approach should be taken to manage the patient who becomes suddenly difficult to oxygenate or ventilate.

An opioid (e.g., fentanyl or morphine) and a sedative agent (e.g., midazolam by intermittent bolus or infusion, or propofol by infusion) are commonly used for analgesia and sedation. Ketamine can provide both sedation and analgesia and is often used for children and patients with reactive airways disease. Prolonged neuromuscular paralysis can usually be avoided by the use of adequate sedation and analgesia (see Chapter 1). If neuromuscular blockade is required, a competitive, non-depolarizing agent, such as pancuronium, vecuronium, or rocuronium, is often selected.

Endotracheal suctioning should be performed regularly. The appropriate frequency is a balance between the need for clearing secretions (especially in pulmonary edema or asthma) and the disadvantage of interrupting ventilation, which can sacrifice gains in alveolar recruitment by allowing airway pressures to fall, even very briefly, to atmospheric levels. Orally intubated patients should have a bite-block placed to protect the endotracheal tube.

Complications

PPV is a lifesaving therapy. However, its use is associated with complications that can become quickly life-threatening, and it is important for emergency physicians to be familiar with common problems associated with PPV. Most of these result from changes in thoracic physiology when positive pressure is present for part or all of the respiratory cycle and are outlined in Box 2-1. Many of these are discussed elsewhere in this text.

Acute difficulty with oxygenation or ventilation, or the development of high airway pressures in a previously calm patient, may indicate undersedation or inadequate analgesia. Additional sedation is administered in concert with a systematic search for patient or device-associated abnormalities. The differential diagnosis, after initial acclimatization, includes ETT migration, ETT occlusion, pneumothorax, bronchospasm, pulmonary edema, acute pulmonary embolism, dynamic hyperinflation, abdominal distention, mechanical failure of the ventilator, and patient-ventilator asynchrony. ETT placement can be checked by capnometry, physical examination, and chest radiography. ETT patency should be assessed by passing a suction catheter. In patients with copious secretions, the existence of a mucous plug acting as a “ball valve” in the endotracheal tube must be considered. This phenomenon presents as a sudden decrease in exhaled volume and elevated 

The diagnoses of pulmonary edema, pneumothorax, and bronchospasm can be made clinically, with chest radiography used as an adjunct. Pulmonary embolism in a ventilated patient may be an even more elusive diagnosis than in other ED patients. Abdominal distention should be apparent on physical examination and is relieved by passage of a nasogastric or orogastric tube. Dynamic hyperinflation and ventilator malfunction may be diagnosed by momentarily disconnecting the ventilator. In the former circumstance, allowing full exhalation results in improvement; in the latter, the patient can be ventilated satisfactorily with a bag and 100% oxygen.

Patient-ventilator asynchrony may indicate incorrect ventilator mode selection, improper flow trigger sensitivity for A/C or SIMV modes, dynamic hyperinflation, or poor tolerance of mechanical ventilation despite sedation. In the last case, there is an indication for increased sedation and, if necessary, neuromuscular blockade.

Patients treated in the ED with NPPV generally should not be given sedatives or major analgesics because preservation of respiratory drive is essential to the use of this technique. Small, incremental doses of benzodiazepines for patients who have difficulty tolerating the face mask or nose mask may be useful. Successful application of noninvasive methods is an acquired skill that takes advantage of not just drugs but of a calming bedside approach to frequently terrified patients. The authors’ experience suggests that allowing family members to stay at the bedside to offer reassurance is often very helpful during the use of NPPV.

Intrinsic PEEP is an important issue, usually in patients with obstructive lung disease. In these cases, the expiratory flow rate is less than normal because of diminished elastic recoil from small airway obstruction (in emphysema) or because of dynamic airflow obstruction during exhalation (in reactive airway disease), or both. The time needed for intrapulmonary pressures to fall to ambient levels at the end of exhalation is prolonged. In spontaneously breathing intubated patients, iPEEP contributes to respiratory failure because this pressure must be matched by deep negative pressures generated by the respiratory bellows in order to initiate inhalation. In mechanically ventilated patients, failure to anticipate prolonged expiration in patients with chronic obstructive or severe reactive lung disease risks setting a respiratory rate too high to allow complete exhalation. Breath stacking results, and unexpectedly high PIPs, patient distress, and hypotension can occur. In patients with chronic lung disease or severe asthma exacerbations who suddenly develop hypotension or become difficult to mechanically ventilate, an appropriate measure is to temporarily discontinue mechanical ventilation by switching to bag-valve breathing with deliberately prolonged exhalation. If this corrects the problem, then mechanical ventilation can be resumed by either using a slower respiratory rate or often with the aid of a respiratory therapist, customizing the inspiratory/expiratory duty cycle to allow the patient more time to exhale.

Special Clinical Circumstances

In the following five common clinical indications for mechanical ventilation in the ED, special fine-tuning adjustments to the guidelines offered previously may be appropriate (Table 2-1).
### Acute Exacerbation of Chronic Obstructive Pulmonary Disease

In treating patients with COPD on the ventilator, respiratory acidosis should be corrected gradually over hours. Overcorrection or too-rapid correction of hypercapnia and acidosis may result in metabolic alkalosis, hypokalemia, and hypophosphatemia. Hypoxemia usually is easily correctable by increasing $\text{Fi}_2$. Target values for $\text{Pao}_2$, $\text{Paco}_2$, and pH should reflect the patient’s predicted (or known) baseline function rather than usual “normal” values.

The other major goal in the mechanical ventilation of patients with COPD is normalization of lung volume. Air trapping and resultant iPEEP in a patient with COPD increases the work of breathing and the likelihood of barotrauma with mechanical ventilation. Strategies used to address this problem center on reducing iPEEP. When inadequate expiratory time is allowed in the COPD patient, air trapping is exacerbated with each inspiration; this dynamic hyperinflation eventually results in a sufficiently high iPEEP that any additional breath necessarily overinflates the thorax. The immediate remedy for this problem is to disconnect the patient from the ventilator momentarily, allowing complete exhalation. The ongoing solution is to build adequate expiratory time into the ventilator settings. The rate should be kept as low as possible for patients with COPD, and the expiratory time should be maximized by increasing the I/E ratio to 1:3 or 1:4. The TV also should be minimized to reduce exhaled volumes. Often patients with COPD require higher flow rates ($\geq 100 \text{ L/min}$) during inspiration to minimize inspiratory time. This approach allows more of the ventilatory cycle to be spent in exhalation. Each of these modifications in the settings reduces iPEEP.

The iPEEP also may be reduced by the use of bronchodilators and corticosteroids. These agents increase inspiratory muscle strength and reduce the amount of secretions in the bronchial lumen, both of which decrease the work of breathing. Finally, iPEEP can be replaced in part by extrinsic PEEP. PEEP at a level of no more than the measured iPEEP (some authors suggest no more than 85% of iPEEP) unloads the work required to maintain iPEEP and allows the recruitment of the muscles providing the inspiratory effort. A consensus statement has suggested that BiPAP should be the initial ventilatory assistance modality of choice in COPD exacerbation.

### Status Asthmaticus

Interventions aimed at reducing hypercapnia in ventilated patients with status asthmaticus may result in dynamic hyperinflation and barotrauma. The best approach in these patients, similar to that used in COPD, is small TV and high inspiratory flow rates to reduce inspiratory time and peak airway pressures. Airway pressures also can be lowered by permissive hypercapnia, which uses a low TV (5–8 mL/kg) and relatively low rates (8–10 breaths/min) to prevent excessive alveolar distention. $\text{Paco}_2$ is allowed to remain at supranormal values without ventilatory correction. The primary goal of permissive hypercapnia is the reduction of lung volume (and iPEEP) and the risk of barotrauma, while maintaining adequate oxygenation. This approach has not been studied thoroughly under controlled conditions, but permissive hypercapnia has potential applicability in status asthmaticus, acute respiratory distress syndrome, and severe COPD exacerbations. Occasional external chest compression also may be useful in assisting exhalation in asthma. This concept has shown promise in animal and uncontrolled human trials.

### Acute Lung Injury

Acute lung injury (ALI) typically develops over several hours but may become evident in the ED. Pathophysiologically it is characterized by heterogeneous noncardiogenic pulmonary edema and surfactant failure that produces poor lung compliance and hypoxia. Pressure-limited special modes may be the optimal means of ventilating patients with ALI, but these techniques are often unavailable in the ED. On standard ventilators, settings should be adjusted to keep PEEP and $\text{Fi}_2$ as low as possible. Small TV (6–8 mL/kg) and fast rates (20–25 breaths/min) are indicated. Although PEEP is considered primary therapy for ALI, these patients are highly susceptible to barotrauma. The risk of oxygen toxicity in ALI also is high and can be minimized by reducing the inspired oxygen concentration to the lowest level that maintains safe hemoglobin saturation levels. Sustained supraphysiologic oxygen tensions worsen inflammation. Iatrogenic barotrauma includes both mechanically induced tissue injury and the introduction of extrapulmonary air, such as pneumothorax or

<sup>+</sup>CMV is the appropriate mode when the patient is apneic or paralyzed.

†PEEP in air-trapping diseases should not exceed measured intrinsic PEEP.

‡Permissive hypercapnia, a ventilatory strategy that can be employed in multiple modes.

Rate should be set based on desired $\text{Paco}_2$. A/C, assist/control (ventilation); ARDS, acute respiratory distress syndrome; CMV, controlled mechanical ventilation; Fi<sub>O</sub>, fraction of inspired oxygen; I/E, inspiratory/expiratory ratio; IMV, intermittent mandatory ventilation; PEEP, positive end-expiratory pressure; SIMV, synchronized intermittent mandatory ventilation; TV, tidal volume.

When using a pressure-cycled ventilator, set pressures to deliver desired TV. After 20 minutes on initial settings, arterial blood gases should be checked so that settings and down-titrations of Fi<sub>O</sub> can be modified appropriately.
pneumomediastinum, due to airspace rupture. Repetitive opening and closing of alveoli lead to shear stress and worsening inflammation. Box 2-2 lists recommendations for minimizing the potential complications of PPV in the setting of ALI; these settings are often appropriate for other applications of mechanical ventilation as well. Collectively, this is often referred to as open lung approach.25

Cardiogenic Shock and Pulmonary Edema

The ventilatory management of pulmonary edema with cardiogenic shock is complicated by the adverse effect of applied PEEP, which is ordinarily a primary mode of therapy for pulmonary edema, on cardiac output. A reasonable compromise is to use only sufficient PEEP to allow titration of the inspired oxygen concentration. Patients in cardiogenic shock require invasive hemodynamic monitoring. Hemodynamic and ventilatory parameters must be followed in tandem to achieve optimal benefit. Patients with less severe pulmonary edema secondary to CHF often may benefit from noninvasive ventilatory support while receiving appropriate pharmacologic therapy. CPAP and BiPAP have been studied in this setting, and one study indicated that there may be little difference between the two modes in either safety or efficacy.26

Hypovolemic Shock

Appropriate volume resuscitation is the optimal means of managing respiratory compromise after trauma or with other causes of hypovolemic shock (e.g., massive gastrointestinal hemorrhage). PPV may exacerbate hypotension in hypovolemic patients. Patients in shock should be ventilated with 100% oxygen at a rate and TV predicted to produce near-physiologic PaCO2. PEEP generally should be avoided until circulating volume is restored.

OUTCOMES

When NPPV is successful (i.e., when ETT-mechanical ventilation is avoided), several potential therapeutic, patient comfort, and fiscal benefits are derived. The advantages of NPPV over ETT-mechanical ventilation include (1) preservation of speech, swallowing, and physiologic airway defense mechanisms; (2) reduced risk of airway injury; (3) reduced risk of nosocomial infection; and (4) decreased length of stay in, and need for admission to, the intensive care unit (ICU) because less weaning and less intensive monitoring are necessary.8,27-30

Patients treated with NPPV have an increased risk of pulmonary barotrauma, aerophagia, and pressure stress to the face compared with intubated and ventilated patients. (BiPAP is a leak-tolerant system so that pressure sores are a much less common complication of extended BiPAP support than of CPAP.) In two series, patients successfully supported in the ED with NPPV usually could be admitted to a telemetry unit instead of an ICU, with significant cost savings.13,29 Uncontrolled studies without definitive inclusion criteria found NPPV successful in avoiding ETT-mechanical ventilation in 60 to 90% of patients.14 One study31 showed increased mortality rates from the use of NPPV, which was attributed to a delay in necessary intubation; the study suffered from selection bias, however, and its results have not been corroborated.32 In a prospective trial of NPPV in acute cardiogenic pulmonary edema, NPPV produced more improvement in subjective dyspnea, tachycardia, and acidosis at 1 hour compared to standard oxygen therapy, but did not produce a difference in mortality at 30 days.10

Treatment of mechanically ventilated patients usually extends beyond the ED. Adequate resuscitation and stabilization are the primary ED goals so that more focused therapy of the underlying problems can be pursued in the ICU. Occasionally, patients are extubated in the ED, most often those intubated solely for airway protection when the initial insult has been reversed or adequately tolerated. Adequate ventilatory drive and oxygen must be confirmed before ED extubation; before attempting to discontinue mechanical ventilation, patients should have a respiratory rate less than 30 breaths/minute, PEEP 5 cm H2O or less, and Pao2 greater than 60 mm Hg with FiO2 less than 60%. NPPV may serve as a bridge between mechanical and spontaneous ventilation.

KEY CONCEPTS

- Not all patients who require intensive ventilatory support in the ED require endotracheal intubation-mechanical ventilation. Careful patient selection for noninvasive ventilatory support may spare some patients invasive therapy and its attendant risk of complications.
- TV of 6 to 8 mL/kg, rate of 12 to 14 breaths/minute, FiO2 of 1.0 is a reasonable starting point for mechanical ventilator settings for patients whose primary pathology is not pulmonary. For patients with pulmonary pathology, settings specific for the cause of the patient’s respiratory failure should be used, then carefully adjusted based on clinical response.
- Sudden difficulty in the treatment of patients receiving NPPV is usually the result of intolerance, inadequate ventilation or oxygenation, or air trapping. Intolerance should not be assumed until other causes are excluded.
- Sudden difficulty in the treatment of patients receiving mechanical ventilation should prompt a quick and systematic evaluation for tube, ventilator, airway pressures, and physiologic problems; such difficulties must not be automatically assumed to result from oversedation. This frequently starts with disconnecting the ventilator from the tube and temporarily bagging with FiO2 of 1.0.
- The goal of therapy in many patients is not prompt normalization of blood gas parameters but may be relief of significant work of breathing. Slow correction to a patient-specific baseline likely results in significantly better clinical outcomes.
PERSPECTIVE

To monitor means to measure or observe a physiologic parameter either continuously or intermittently. Monitoring devices provide a “snapshot in time” and a window into the clinical status of the patient, detecting deterioration, tracking improvement, or measuring the effects of interventions. Monitoring parameters such as clinical observation, routine vital sign measurement, and electrocardiographic monitoring are basic tools in the practice of emergency medicine.

This chapter focuses on the following monitoring modalities: oxygenation monitoring with pulse oximetry, ventilation monitoring with end-tidal carbon dioxide (ET\textsubscript{CO}\textsubscript{2}) measurement and waveform analysis, and hemodynamic monitoring with noninvasive blood pressure (BP) measurement. Fetal monitoring immediately after maternal trauma is also briefly discussed.

NONINVASIVE BLOOD PRESSURE MEASUREMENT

Automatic noninvasive BP measurement has become a popular and, if applied appropriately, an accurate method of determining BP. Advantages include more time for staff to attend to other tasks, timed repetition of BP measurements, continuous display of the systolic pressure, and a multiparameter display (e.g., systolic, diastolic, and mean BP; pulse rate).

Two types of noninvasive BP measurement devices are currently available:

1. Cuff-type
2. Radial arterial noninvasive waveform analysis

The noninvasive cuff-type devices use a detection system based on auscultatory, oscillometric, or Doppler principles.\textsuperscript{1,2} Automatic oscillometric devices determine BP by electronically determining the pulse amplitude. This method and Doppler are the most accurate of the indirect methods. The cuff is automatically inflated at predetermined intervals to a preset level. As the machine gradually deflates the cuff, it senses the amplitude of the oscillations (pulsations) transmitted to the cuff by movement of the arterial wall under the cuff. An abrupt increase in the magnitude of the oscillation signals an opening of the artery and an increase in volume under the cuff; this is the systolic pressure. The magnitude of the oscillation increases to a peak and then falls rapidly. The point where there is no longer an alteration in the magnitude of the oscillation is the diastolic pressure. Some devices calculate the mean arterial pressure (MAP); others identify it as the cuff pressure at the point of largest oscillation.\textsuperscript{1}

Noninvasive cuff-type oscillometric devices can be cycled every 15 to 20 seconds in the “STAT” mode when necessary to provide rapid but intermittent BP readings.\textsuperscript{3} Accuracy during rapid cycling is the same as during less frequent sampling, but to prevent pressure injury from the high frequency of cycling, most cuff-type automatic BP devices revert to the intermittent mode after a brief period of rapid cycling.

The shortcomings of cuff-based noninvasive BP monitoring are those of any cuff measurement technique; patients with obese arms, uncooperative moving patients, and patients with very high or very low BP. Even with these limitations, automatic devices are more accurate and reliable than manual auscultation in patients with very low or high BP because the sensing devices are more sensitive than the human ear.\textsuperscript{2} The cycle length of the inflation-deflation sequence of the older devices was exceedingly long and led to frequent failure. The newer devices have rectified this problem.

A newer method of continuous, noninvasive BP monitoring measures radial artery BP and pulse rate every 12 to 15 beats. The Vasotrac (Medwave Inc., Arden Hills, St. Paul, MN) device measures BP and pulse rate and displays a radial arterial pressure waveform.\textsuperscript{4} It consists of a reusable circular sensor (diameter 1.20″; width 0.35″) which is strapped over the radial artery at the wrist. The wrist sensor module is designed to measure only the pulsatile energy perpendicular to the artery, using cyclical compression and decompression. The processor requires 12 to 15 consecutive beats without interference (movement artifacts) to obtain adequate energy information to generate the pulsatile calibrated beat.\textsuperscript{4}

Although the device is expensive and requires the patient to remain relatively still, a limited number of studies have demonstrated that this noninvasive method of continuous BP measurement is comparable to that provided by an invasive arterial catheter.\textsuperscript{4,6}

The most accurate method of measuring BP is with an intraarterial catheter transduced to an electronic display. The ability to identify beat-to-beat variability, respiratory variation, and longer trends is unsurpassed. In addition, arterial catheter placement enables frequent sampling of arterial blood without additional arterial punctures. Arterial pressure monitoring is
used increasingly in EDs, particularly as lack of available beds in the intensive care unit mandates longer stays in the emergency department (ED) for critically ill patients. The risk of arterial injury or thrombosis related to arterial line insertion is low, but real, and can result in vascular compromise. Situations when noninvasive BP measurement may prove inadequate and invasive monitoring via an arterial catheter should be considered include:

1. Exceedingly high (>250 mm Hg systolic) or low (<80 mm Hg systolic) pressures. Although the invasive methods are also less accurate at these extremes, the error is significantly less than with noninvasive methods.
2. Patients requiring continuous BP monitoring (e.g., rapid antihypertensive therapy with sodium nitroprusside) due to the potential for rapid fluctuations in BP.
3. In impending shock states, the best chance to insert an arterial line may be in the ED while the arterial pulse is still readily palpable, although this should not delay transferring the patient to a more appropriate location for definitive care.
4. Patients with anatomic abnormalities (e.g., no suitable limb to undertake noninvasive measurement, morbidly obese patient).
5. Conditions where frequent arterial sampling is required. The requirement in such cases is for vascular access rather than the monitoring per se. Patients who are ill enough to require frequent arterial sampling usually benefit from continuous arterial BP monitoring.

### BLOOD GAS MONITORING

Although the ability to monitor oxygen utilization at the cellular level might be considered ideal, current technology permits less precise measures of performance. Transcutaneous oxygen and CO2 monitoring, conjunctival oxygen pressure, pulse oximetry, and ETCo2 monitoring (capnography, capnometry) are all used to indicate the adequacy of pulmonary gas exchange and arterial blood gas (ABG) tensions and to assess ventilatory efficacy.

#### Pulse Oximetry

The pulse oximeter provides a rapid, noninvasive, and continuous measurement of arterial oxygen saturation that has become a uniform standard for patient monitoring throughout medicine. Oximeters are easy to use and interpret, pose no risk to the patient, and are relatively inexpensive, although reliable interpretation of the information given by these devices requires an appreciation of the limitations of the technology.

Transmission oximetry is the most common type of oximetry used in clinical practice. Transmission oximetry is based on differences in the optical transmission spectrum of oxygenated and deoxygenated hemoglobin. In addition to arterial hemoglobin, other absorbers in the light path include skin, soft tissue, and venous and capillary blood. Pulse oximeters measure the pulse variations in red and infrared (IR) light transmitted through a tissue bed. Data averaged over several arterial pulse cycles are then presented as oxygen saturation as measured using pulse oximetry (SpO2). Studies have shown an excellent correlation between arterial hemoglobin oxygen saturation and SpO2 in patients with normal perfusion.

The limitations of oximetry technology are related to alterations in local or systemic perfusion and severe vasoconstriction (e.g., shock, hypothermia), excessive movement, interference with transfer through the nail bed (e.g., from synthetic fingernails or nail polish), and alterations in hemoglobin (e.g., severe anemia, abnormal hemoglobins). Carboxyhemoglobin (COHb) and methemoglobin (MetHb) contribute to light absorption and cause errors in oximetry readings. The pulse oximeter senses COHb as though it were mostly oxyhemoglobin and provides a falsely high reading. MetHb produces a large pulsatile absorbance signal at both the red and IR wavelengths, which forces the absorbance ratio toward unity, corresponding to an SpO2 of 85%. Thus, with high levels of MetHb, the SpO2 is erroneously low when the arterial saturation is above 85% and erroneously high when the arterial saturation is below 85%. Erroneously high readings (about 3–5%) and a higher incidence of failure to detect signals have been reported in dark-skinned races.

Signals tend to be weaker from ears than from fingers, except in hypotension or peripheral vasoconstriction, but ear responses are faster.

Pulse oximetry is particularly useful in the ED evaluation of patients with acute cardiopulmonary disorders such as bronchiolitis, asthma, heart failure, and chronic obstructive pulmonary disease (COPD) and in patients with drug-induced or traumatic alterations in consciousness. It is mandatory in patients undergoing procedural or deep sedation and in those requiring definitive airway management. However, it is valuable in any patient for whom continuous knowledge of oxygen levels is helpful in their treatment. Continuous monitoring may indicate the insidious development of shock as vasoconstriction and deterioration of signal detection develop. Improvements in pulse oximeter technology have resulted in improved accuracy and reliability during patient motion. In short, this valuable device has become an established component of the monitoring armamentarium of emergency medicine.

However, adequate oxygen saturation does not ensure adequate ventilation, particularly in patients with decreased levels of consciousness. ETCo2 monitoring is required for accurate assessment of ventilation.

### End-Tidal Carbon Dioxide Monitoring

The concentration of CO2 in an exhaled breath is intrinsically linked to tissue metabolism, systemic circulation, and ventilation. Capnography is the graphic record, represented as a waveform, or capnogram, of the instantaneous CO2 concentrations in respired gases during a respiratory cycle. Capnography provides continuous, real-time, breath-to-breath feedback on the clinical status of the patient, allows the clinician to determine the baseline ventilatory status and to track changes over time. Capnography is also a diagnostic monitoring modality because certain disease conditions are associated with characteristic waveforms. Although the concentrations of CO2 can be displayed continuously through the respiratory cycle, by convention only the maximum CO2 concentration at the end of each tidal breath, the ETCO2, is ordinarily displayed. Capnometry is the quantitative measurement of ETCO2 displayed as a number without a waveform. Colorimetric detectors use color scales to estimate ranges of ETCO2, but are not sufficiently accurate to give quantitative measurements. Their use is therefore limited to confirmation of correct endotracheal tube (ETT) placement and its continuous location in the trachea.

Although originally used during general anesthesia in the operating room, ETCO2 monitoring has become a standard monitoring modality in the ED and nonhospital medical setting.

Carbon dioxide monitors are configured as either sidestream or mainstream, depending on the location of the photoelectric
detector or sensor. Mainstream devices measure CO₂ directly from the airway, with the sensor attached directly to the ETT. Sidestream devices, more commonly used by emergency medical service (EMS) personnel and in the ED, aspirate a sample of gas through tubing into a sensor located inside the monitor, and are used for both intubated and nonintubated patients. They are lightweight and may be integrated into special nasal-oral cannulae that simultaneously sample CO₂ and deliver low-flow oxygen, allowing for continuous oxygen delivery during procedural sedation and analgesia.

Several recent studies, however, have shown high concordance between ET and deliver low-flow oxygen, allowing for continuous oxygen delivery during procedural sedation and analgesia.

Colorimetric CO₂ detectors use pH-sensitive filter paper impregnated with metacresol purple, which changes color from purple (<4 mm Hg CO₂) to tan (4–15 mm Hg CO₂) to yellow (>20 mm Hg CO₂) depending on the concentration of CO₂ (Fig. 3-1B). The indicator, housed in a plastic casing, is inserted between the ET and the ventilator bag and detects changes on a breath-by-breath basis. They are also inexpensive and easy to use, and should be available in every ED and on every EMS unit that performs intubation for confirmation of ETT placement if capnography or capnometry is not available.

In patients with normal cardiopulmonary function, there is a close correlation between alveolar CO₂ (Paco₂) and arterial CO₂ (PaCO₂). The ET(ETCO₂) is usually 2 to 5 mm Hg less than the Paco₂ because of the contribution of physiologic dead space gas to the end-tidal gases. Conditions that affect ventilation-perfusion ratios (including pulmonary embolism), cardiac arrest, hypovolemia, obstructive lung disease, and the lateral decubitus position, can widen the Pa-ETCO₂ gradient. Several recent studies, however, have shown high concordance between ET(ETCO₂) and Paco₂ in adult asthmatics and in children with moderate and severe respiratory distress from bronchiolitis, asthma, and pneumonia. Although ET(ETCO₂) may not always accurately reflect the absolute Paco₂ in critically ill patients, it is still valuable in detecting ventilatory trends and identifying sudden airway events.

Analysis of the shape of the capnogram can yield valuable diagnostic information. A normal capnogram has four phases (Fig. 3-1A). Phase 1-2 represents a CO₂-free portion of the respiratory cycle. Most often this is the inspiratory phase, although it may represent apnea or a disconnection of the device from the patient. An elevation of this baseline above zero implies rebreathing of CO₂, as in increased dead space in the circuit or contamination of the sensor.

Phase 2-3, the rapid upstroke of the curve, represents the transition from inspiration to expiration and the mixing of dead space and alveolar gas. Prolongation of phase 2-3 occurs with obstruction to expiratory gas flow (e.g., obstructive lung disease, bronchospasm, kinked ETT) or leaks in the breathing system.

Phase 3-4, the alveolar plateau, represents the predominance of CO₂-rich alveolar gas in the breath stream and tends to slope gently upward with the uneven emptying of alveoli. Point 4 (the ET(ETCO₂)) represents the maximum CO₂ concentration in each breath and is the number that appears on the monitor. The slope of this phase can be increased by the same obstructive factors that increase the slope of phase 2-3 and is also a normal physiologic variation in pregnancy. A dip in the plateau indicates a spontaneous respiratory effort during mechanical ventilation, as in hypoxia, hypercarbia, or inadequate anesthesia (Fig. 3-1C).

Phase 4-5, the inspiratory downstroke, is a nearly vertical drop to baseline. This slope can be prolonged and blend in with the expiratory phase in endotracheal cuff leaks (Fig. 3-1D). Abnormal respiratory patterns that are fast or chaotic limit the usefulness of ET(ETCO₂) monitoring because characteristic waveform patterns are difficult to discern.

Capnography is used in the ED in many intubated and nonintubated clinical scenarios. It can confirm ETT placement in the trachea, continuously monitor tube position in the trachea during transport, provide qualitative and quantitative methods of assessing cardiac output, gauge effectiveness of cardiopulmonary resuscitation (CPR) during cardiac arrest, determine prognosis in CPR and in trauma, maintain appropriate ET(ETCO₂) levels in patients with elevated intracranial pressure, estimate Paco₂ in patients with normal lung function, aid in the detection and diagnosis of pulmonary embolism, assess response to treatment in patients with acute respiratory distress, determine adequacy of ventilation in patients with altered mental status (including drug-induced alterations in consciousness during procedural sedation and analgesia), assess ventilatory status of actively seizing patients, and help detect metabolic acidosis.

Along with visualizing tracheal rings on bronchoscopy, capnography is the other "gold standard" used to confirm intubation of the trachea (see Chapter 1). Misleading ET(ETCO₂) readings can occur with esophageal intubation after bag or mask ventilation and ingestion of carbonated beverages or antacids.
However, detection of ET\textsubscript{CO\textsubscript{2}} usually ceases after six breaths and, if capnography is used, the tracings look abnormal.\textsuperscript{28} ET\textsubscript{CO\textsubscript{2}} is also falsely elevated for 5 to 10 minutes after injection of sodium bicarbonate.\textsuperscript{29} In nonarrest settings the ET\textsubscript{CO\textsubscript{2}} approaches 100\% sensitivity and specificity in confirming correct tube placement and is also useful for monitoring for accidental extubation.

Airway, breathing, and circulatory assessment of critically ill or injured patients can be rapidly determined using ET\textsubscript{CO\textsubscript{2}} values and the capnogram.\textsuperscript{30} The presence of a normal capnogram denotes a patent airway and spontaneous breathing, and normal ET\textsubscript{CO\textsubscript{2}} levels indicate adequate ventilation and perfusion. Capnography can therefore be used to assess critically ill patients (including victims of chemical terrorism with nerve gas exposure) and patients who are actively seizing.\textsuperscript{30,31} Unlike pulse oximetry and electrocardiography, capnographic measurement is airway-based and therefore is not subject to motion artifact. It also provides reliable readings in low perfusion states.\textsuperscript{32}

Animal and human studies have shown that ET\textsubscript{CO\textsubscript{2}} is a useful noninvasive measurement that is highly correlated with cardiac output and is the earliest indicator of return of spontaneous circulation (ROSC) in CPR.\textsuperscript{33-35,40} ROSC is heralded by an almost immediate increase in ET\textsubscript{CO\textsubscript{2}} from baseline. Multiple studies showed that ET\textsubscript{CO\textsubscript{2}} has prognostic value in terms of mortality during CPR.\textsuperscript{35-39} No patient with a mean ET\textsubscript{CO\textsubscript{2}} less than 10 mm Hg after 20 minutes of CPR survived, giving ET\textsubscript{CO\textsubscript{2}} measurement a high negative predictive value for failure of resuscitation. Despite these promising findings, capnography requires further prospective validation to confirm its utility as a prognostic tool in cardiac arrest.

Capnography is the only ventilation monitoring modality that is accurate and reliable in actively seizing patients.\textsuperscript{30,31} Capnographic data (capnogram, ET\textsubscript{CO\textsubscript{2}}, respiratory rate) can be used to distinguish among actively seizing patients with apnea (flatline waveform, no ET\textsubscript{CO\textsubscript{2}} readings, and no chest wall movement), ineffective ventilation with low tidal volume breathing (small capnograms, low ET\textsubscript{CO\textsubscript{2}}), and effective ventilation (normal capnogram, normal ET\textsubscript{CO\textsubscript{2}}).

Capnography can also rapidly detect the common airway, respiratory, and central nervous system complications associated with the nerve agents in chemical terrorism, including apnea, upper airway obstruction, laryngospasm, bronchospasm, and respiratory failure.\textsuperscript{37,38}

Capnography provides dynamic monitoring of ventilatory status in patients with acute respiratory distress, such as from asthma, bronchiolitis, COPD, congestive heart failure, croup, and cystic fibrosis. By measuring ET\textsubscript{CO\textsubscript{2}} and respiratory rate with each breath, capnography provides instantaneous feedback on the clinical status of the patient. Respiratory rate is measured directly from the airway by nasal-oral cannulae, providing a more reliable reading than impedance respiratory monitoring. In upper airway obstruction and laryngospasm, for example, impedance monitoring detects chest wall movement, interprets this as a valid breath, and displays a respiratory rate, even though the patient is not ventilating. In contrast, capnography detects no ventilation and shows a flatline capnogram.

Bronchospasm in obstructive lung disease leads to upward slanting of the expiratory plateau of the capnogram (Fig. 3-2, middle panel). Changes in ET\textsubscript{CO\textsubscript{2}} over time and the slope of this phase of the capnogram have been shown to correlate well with spirometric measurements (forced expiratory volume in 1 second [FEV\textsubscript{1}] and peak expiratory flow rate [PEFR]).\textsuperscript{41,43} Capnography has the advantage of being independent of effort, gender, age, and height and is a useful objective measure in asthmatic patients who are unwilling or unable to cooperate with spirometry (e.g., young children, ventilated patients, and patients in acute respiratory distress). Capnography can also be used to distinguish obstructive from restrictive lung disease.\textsuperscript{44} Characteristic capnographic patterns associated with restrictive and obstructive lung disease are shown in Figure 3-2 (bottom panel).

Capnography can also detect the common adverse airway and respiratory events associated with procedural sedation and analgesia.\textsuperscript{17} Capnography is the earliest indicator of airway or respiratory compromise and displays an abnormally high or low ET\textsubscript{CO\textsubscript{2}} before pulse oximetry detects a falling oxyhemoglobin saturation, especially in patients receiving supplemental oxygen. Both central and obstructive apnea can be almost instantaneously detected by capnography. Capnography may be more sensitive than clinical assessment of ventilation in the detection of apnea. In a recent study, 10/39 (26\%) of patients experienced 20-second periods of apnea during procedural sedation and analgesia. All ten episodes of apnea were detected by capnography but not by the anesthesia providers.\textsuperscript{44}

Obtunded or unconscious patients, including those with alcohol intoxication, intentional or unintentional drug overdose, and postictal patients (especially those treated with benzodiazepines), may have impaired ventilation. Capnography can differentiate between postictal patients with effective ventilation and those with ineffective ventilation as well as provide continuous monitoring of ventilatory trends over time to identify those patients at risk for respiratory depression and respiratory failure.

In addition to its established uses for assessment of ventilation and perfusion, capnography is a valuable tool for assessing metabolic status. Recent studies have shown that ET\textsubscript{CO\textsubscript{2}} and serum bicarbonate (HCO\textsubscript{3}) are linearly correlated in diabetes and in pediatric gastroenteritis, and ET\textsubscript{CO\textsubscript{2}} can be used as an indicator of metabolic acidosis in these patients (Figs. 3-3 and 3-4, respectively).\textsuperscript{45,46} As a patient becomes acidotic, HCO\textsubscript{3} decreases and a compensatory respiratory alkalosis develops with an increase in minute ventilation and a resultant decrease in ET\textsubscript{CO\textsubscript{2}}. The more acidotic, the lower the HCO\textsubscript{3}; the higher the respiratory rate, the lower the ET\textsubscript{CO\textsubscript{2}}. Furthermore, ET\textsubscript{CO\textsubscript{2}} can be used to distinguish diabetics in ketoacidosis (metabolic acidosis, compensatory tachypnea, low ET\textsubscript{CO\textsubscript{2}}) from those who are not (nonacidotic, normal respiratory rate, normal ET\textsubscript{CO\textsubscript{2}}). A similar association between ET\textsubscript{CO\textsubscript{2}} and HCO\textsubscript{3} was demonstrated in children with gastroenteritis, in whom an ET\textsubscript{CO\textsubscript{2}} = 31 mm Hg is 76\% sensitive and 96\% specific for the presence of metabolic acidosis (Fig. 3-4).\textsuperscript{47}
Trauma occurs in about 7% of pregnant females. Although maternal mortality rates in trauma do not differ from those for nonpregnant females with comparably severe injury, fetal mortality rates increase over those for pregnant women who have not suffered a traumatic injury. The American College of Obstetricians and Gynecologists recommends that the pregnant patient with a viable fetus undergo fetal monitoring for 2 to 6 hours after an injury characterized with any degree of abdominal jarring.

Fetal monitoring is used by emergency physicians to detect occult fetal distress and inform therapy and referral. Persistent fetal tachycardia, bradycardia, loss of baseline variability or decelerations following uterine contractions (e.g., Braxton Hicks contractions), and uterine hyperactivity require urgent obstetric consultation. Although most emergency medicine residents are trained to recognize the cardiotocographic findings indicative of fetal distress, most EDs do not have this monitoring equipment available. Ultrasound machines are used widely to measure and monitor fetal heart rate.

**CEREBRAL FUNCTION MONITORING**

The Bispectral index (BIS) monitors analyses and processes a patient’s electroencephalogram during sedation to produce a single number—the Bispectral index. This unitless number, ranging from 0 to 100, is used as an indicator of the depth of sedation, with 0 representing EEG silence and 100 a fully awake adult.

BIS monitoring has been studied in the ED in an attempt to objectify sedation endpoints by titrating to a target BIS score. The evidence of its ability to reliably reflect depth of sedation is conflicting, however. More importantly, the threshold beyond which ventilatory compromise occurs has not been determined, further limiting the usefulness of routine BIS monitoring for sedation in the ED. Gill and colleagues found that BIS monitoring reliably distinguished patients undergoing procedural sedation and analgesia who were sedated to the point of general anesthesia from those with lesser degrees of sedation but did not discriminate mild-to-moderate sedation or moderate-to-deep sedation. The findings of Miner and coauthors supported this contention in that the assignment of a preprocedural BIS target sedation level of moderate or deep procedural sedation did not influence the level of sedation achieved, the rate of respiratory depression, the occurrence of complications, the time to return of baseline mental status, or the success of the procedure. They concluded that the assignment of a preprocedural target sedation level was not an effective means of changing the outcome of procedural sedation in the ED.

In small pediatric ED studies, however, Agrawal and co-workers and Overly and associates found BIS monitoring correlated with clinical sedation scores. Determination of utility and effectiveness on outcome for children undergoing procedural sedation and analgesia awaits larger trials.

**KEY CONCEPTS**

1. Monitoring modalities, when used appropriately, help to identify the effectiveness of interventions, predict deterioration, track the patient’s clinical course, and inform clinical decision-making.
2. ETco2 monitoring, especially capnography, supplements oximetry by providing useful information regarding pathologic conditions and response to therapy.
3. Alarm limits should be adjusted to ensure reasonable warnings are delivered, optimally reducing the number of false alarms. Disabling alarms is dangerous.
PERSPECTIVE

In philosophic terms, shock can be viewed as a transition between life and death. Whether shock results from hemorrhage, sepsis, or cardiac failure, mortality rates exceed 20%.\(^1\)\(^2\)\(^3\) In scientific parlance, shock results from the widespread failure of the circulatory system to oxygenate and nourish the body adequately. In the laboratory the scientist defines the metabolic effect of shock quantitatively, by examining the mechanisms by which shock alters mitochondrial energy transfer, evokes the production of toxic chemicals, and reduces their removal. At the bedside, however, the clinician identifies shock by linking the clinical impression, synthesized from the patient’s history of present illness, age, underlying health status, and general appearance, with quantitative data, including vital signs, blood chemistry, urine output, and direct measurements of oxygenation. When the clinical impression and the quantitative data suggest widespread organ hypoperfusion, emergent resuscitation must restore normal tissue oxygenation and substrate delivery to prevent deterioration into systemic inflammation, organ dysfunction, and death.

At the subcellular level, shock first affects the mitochondria. Mitochondria function at the lowest oxygen tension in the body, but paradoxically, they consume almost all the oxygen used by the body. More than 95% of aerobic chemical energy comes from mitochondrial combustion of fuel substrates (fats, carbohydrates, ketones) plus oxygen (O\(_2\)) into carbon dioxide (CO\(_2\)) and water (H\(_2\)O). Mitochondria therefore have been referred to as the “canaries in the coal mine” because they are affected first in conditions of inadequate tissue perfusion.\(^4\)\(^5\) When mitochondria have inadequate oxygen, the cell catabolizes fuels to lactate, which inexorably accumulates and diffuses into the blood.

Classification

For years, shock has been classified into four broad categories based on Blalock’s 1940 description: hematologic, neurologic, vasogenic, and cardiogenic.\(^6\) This basic organization scheme remains useful today. Box 4-1 outlines five categories of shock that generally have specific mechanisms and treatments.

Epidemiology

The epidemiology of shock in the emergency department (ED) context remains speculative because shock is rarely listed as a primary coding diagnosis and depends on defining criteria. Arterial hypotension, defined as a systolic blood pressure less than 100 mm Hg, is measured at least one time in 19% of ED patients;\(^7\) however, diagnosed traumatic, cardiogenic, or septic shock is less common, constituting about 1 to 3% of all ED visits.

This chapter reviews the metabolic, systemic, and inflammatory responses that occur in all types of circulatory shock and discusses specific pathophysiology of the major causes of shock.

Specific Causes

Hemorrhagic Shock

Hemorrhagic shock results from a rapid reduction in blood volume, which causes baroreceptor activation and leads to vasoconstriction, increased strength of cardiac contraction, and increased heart rate (HR). Cardiovascular response to hemorrhage can vary with underlying cardiopulmonary status, age, and presence of ingested drugs. Responses of HR and blood pressure (BP) are notoriously variable in hemorrhage, so no firm conclusion can be made at the bedside about the presence or absence of hemorrhagic shock simply by evaluating HR and BP.\(^8\) In general, hemorrhage first increases pulse and cardiac contraction, then increases vasoconstriction. Blood loss causes an elevated pulse rate with a slight increase in the diastolic BP, causing the pulse pressure (difference between systolic and diastolic BP) to narrow. As blood loss continues ventricular filling decreases, and cardiac output drops, followed by a reduction in systolic BP. Before the total cardiac output begins to decrease, blood flow to noncritical organs and tissues begins to decrease, and their cells produce and release lactic acid.

Consequently, acidemia often precedes any significant decrease in cardiac output with hemorrhage.\(^9\) However, the blood contains bicarbonate ions that buffer the blood pH, keeping it near neutral, even as lactic acid accumulates in blood. The base deficit, defined as the amount of strong base that would have to be added to a liter of blood to normalize the pH, represents an index of how far the bloodstream has dipped into its reserve of bicarbonate buffer. A normal base deficit is more positive than \(\sim 2\) mEq/L. Accordingly, the arterial and venous blood base deficit can become more negative early in hemorrhage even while blood pH and BP remain in the normal range. The base deficit, therefore, crudely represents the physiologic endpoint that distinguishes trivial blood loss from clinically significant hemorrhage. In addition to
Chemical buffering, the body responds to small reductions in arterial pH by activating brainstem chemoreceptors, which increase minute ventilation, leading to reduced partial pressure of carbon dioxide in arterial gas (Paco₂). After approximately one third of the total blood volume is acutely lost, cardiovascular reflexes can no longer sustain adequate filling of the arterial circuit, and frank hypotension supervenes. Arterial hypotension is generally and arbitrarily defined as an arterial BP below 90 to 100 mm Hg. Usually coincident with the development of hypotension, bicarbonate buffers become overwhelmed, and increased alveolar ventilation becomes ineffective, culminating in reduced arterial pH.

Hemorrhagic shock causes an activation of the hypothalamic-pituitary-adrenomedullary axis, with release of stress hormones that cause glycoegenolysis, lipolysis, and mild hypokalemia. Therefore, in the ED, patients sustaining traumatic hemorrhage generally have an arterial lactate concentration greater than 4.0 mmol/L, a PaO₂ less than 35 mm Hg, and mild hyperglycemia (150–170 mg/dL) and hypokalemia (3.5–3.7 mEq/L). Although hemorrhagic hypotension reduces lung perfusion, arterial hypoxemia should not be attributed simply to blood loss, but instead should prompt investigation for aspiration, airway obstruction, alveolar consolidation, or lung injury.

The second phase of organ injury from hemorrhagic shock occurs during resuscitation. It has been said that the acute phase of hemorrhage “cocks the gun,” and resuscitation “pulls the trigger” to cause organ injury from hemorrhagic shock. During resuscitation, neutrophils become most aggressive, binding to the lung endothelium and causing capillary leaks that characterize the adult respiratory distress syndrome (ARDS). Inflammatory cytokines are liberated during resuscitation, and membrane injury occurs in many cells. In the liver, damage from inflammation and reactive oxygen species from neutrophils is compounded by persistent microschemia. During resuscitation from hemorrhagic shock, the normal balance of vasodilation by nitric oxide (NO) versus vasoconstriction by endothelins becomes distorted, producing patchy centrilobular ischemic damage in the liver, which may produce an immediate rise in blood transaminase levels. A growing body of evidence suggests that resuscitation from hemorrhage exerts greater injury to the heart than the actual hypotensive insult. Depending on the degree of hypotensive insult, the kidney may manifest acute renal insufficiency (e.g., acute tubular necrosis), requiring dialysis. Systemic metabolic changes can impair fuel delivery to the heart and brain, secondary to depressed hepatic glucose output, impaired hepatic ketone production, and inhibited peripheral lipolysis.

Septic Shock

Septic shock can be produced by infection with any microbe, although in as many as half of the cases of septic shock, no organism is identified. One of the most well-studied mediators of sepsis is lipopolysaccharide, contained in the outer cell membrane of gram-negative bacteria. Infusion of lipopolysaccharide into humans or animals produces cardiovascular, immunologic, and inflammatory changes identical to those observed with microbial infection. In recent years, multicenter trials of sepsis have suggested the emergence of gram-positive organisms as the chief cause of sepsis in hospitalized patients. Two lines of reasoning imply that gram-positive sepsis will continue to increase in prevalence:

1. More patients are being treated at home for chronic immunocompromising diseases with indwelling catheters, which serve as excellent portals of entry into the vascular space for Staphylococcus aureus and coagulase-negative staphylococci.

2. The frequency of community-acquired infections caused by antibiotic-resistant gram-positive organisms has greatly increased in recent years, including infections caused by Staphylococcus aureus, Streptococcus pneumoniae, and Streptococcus pyogenes.
Severe shock causes three major effects that must be addressed during resuscitation: relative hypovolemia, cardiovascular depression, and induction of systemic inflammation. Septic shock produces relative hypovolemia from increased venous capacitance, which reduces right ventricular filling. Septic shock often causes absolute hypovolemia from gastrointestinal volume losses, tachypnea, sweating, and decreased ability to drink during development of the illness. Sepsis also induces capillary leak, which leads to relative loss of intravascular volume into third spaces. Recent evidence has shown that septic shock causes myocardial depression simultaneously with vasodepression and capillary leak. Direct measurements of cardiac contractility have shown that cardiac mechanical function becomes impaired early in the course of septic shock, even in the hyperdynamic stages. Multiple mechanisms may explain depressed heart function in sepsis, including actions of specific cytokines (most notably tumor necrosis factor alpha [TNF-α] and interleukin 1 beta [IL-1β]), overproduction of NO by nitric oxide synthase (iNOS), and possibly impairment in mitochondrial oxidative phosphorylation coincident with reduced mechanical efficiency. Evidence indicates that circulating mediators, myocardial cellular injury from inflammation, and deranged metabolism interact synergistically to injure the heart during septic shock. Systemic inflammation causes capillary leak in the lung, which may cause alveolar infiltration characteristic of ARDS early in the treatment of septic shock in up to 40% of patients. With the potential for early development of ARDS, more profound ventilation/perfusion mismatching, and pneumonia or pulmonary aspiration, hypoxemia is more severe with septic shock than hemorrhagic shock.

Cardiogenic Shock

Cardiogenic shock (myocardial pump failure) results when more than 40% of the myocardium undergoes necrosis from ischemia, inflammation, toxins, or immune destruction. Otherwise, cardiogenic shock essentially produces the same circulatory and metabolic alterations observed with hemorrhagic shock. Undoubtedly, impaired baseline cardiac function can contribute to the development of circulatory shock secondary to infection, hemorrhage, or vasodilatory drug overdose. However, when shock results from a pure cardiac cause, severe left ventricular dysfunction is evident on echocardiography early in the course. Patients with severe dysfunction are far more likely to have a cardiogenic cause of shock than patients with normal or moderate left ventricular dysfunction.

### Clinical Features

Patients frequently present to the ED in shock with no obvious cause. Rapid recognition of shock requires the integration of information from immediate history and physical examination, and a diagnosis of shock can be strongly supported by the presence of a worsening base deficit or lactate acidosis. In general, patients with shock exhibit a stress response: they appear ill, pale, often sweating, usually tachypneic or grunting, and often with a weak and rapid pulse (Box 4-2). HR can be normal or low in cases of shock, especially when the patient is taking prescribed drugs that depress HR or the circumstance is complicated by profound hypoxemia. BP initially can be normal because of adrenergic reflexes. Although arterial BP as a sole measurement remains an unreliable marker of circulatory status, the finding of a single systolic BP less than 100 mm Hg in the ED is associated with a threefold increase in in-hospital mortality and a tenfold increase in sudden and unexpected death. The HR/systolic BP ratio may provide a better marker of shock than either measurement alone; a normal ratio is less than 0.8. Urine output provides an excellent indicator of organ perfusion and is readily available with insertion of a Foley catheter. Measuring urine output, however, requires at least 30 minutes to accurately determine if output is normal (>1.0 mL/kg/hr), reduced (0.5–1.0 mL/kg/hr), or severely reduced (<0.5 mL/kg/hr). Point measurements of the arterial lactate concentration and the base deficit can be rapidly performed and provide accurate assessment of global perfusion status. A lactate concentration greater than 4.0 mM or a base deficit more negative than −4 mEq/L predicts the presence of circulatory insufficiency severe enough to cause subsequent multiple organ failure. Once the empirical criteria for circulatory shock are discovered, the next step is to consider the cause of shock. Figure 4-1 is an algorithm of potential decisions to facilitate diagnosis in a patient with undifferentiated shock.

- **Ill appearance or altered mental status**
- **Heart rate >100 beats/min**
- **Respiratory rate >20 breaths/min or Paco₂ <32 mm Hg**
- **Arterial base deficit <−4 mEq/L or lactate >4 mM/L**
- **Urine output <0.5 mL/kg/hr**
- **Arterial hypotension >20 minutes duration**

* Regardless of cause. Four criteria should be met.

Use of the history, vital signs and physical examination documented by outside providers represents a valuable insight into a patient’s physiologic status prior to any medical intervention and can be useful in ED management. Studies suggest that both medical and trauma patients with hypotension prior to being seen in the ED have a three- to fourfold higher in-hospital mortality rate than patients without hypotension.

The primary survey must ensure presence of a patent airway as well as sufficient respiratory effort for adequate oxygenation and ventilation. The physical examination should be performed on an undressed patient and should begin with a quick head-to-toe inspection. Dry mucous membranes suggest dehydration, whereas distended jugular veins suggest cardiac failure or obstruction from pulmonary embolism (PE) or cardiac tamponade. Muffled heart sounds suggest cardiac tamponade, whereas a loud machine-like systolic murmur indicates acute rupture of a papillary muscle or rupture of the interventricular septum. Bilateral pulmonary rales in a patient with a normal rectal temperature help to define the presence of primary left ventricular failure. Wheezing suggests bronchospasm from anaphylaxis or, less likely, cardiac failure or PE. Abdominal tenderness may indicate peritoneal inflammation or occult trauma. Rectal examination may disclose occult gastrointestinal hemorrhage. Rectal temperature should be performed as early as is reasonable on every patient with suspected shock.

The neurologic examination documents responsiveness, cognition, and the presence of any focal deficits. In children, documentation should include level of alertness, response to parents, appropriateness of crying, pupillary function, symmetry of grimace, symmetry of extremity movements, and motor tone in infants.

Laboratory, radiographic, and other ancillary data should be ordered to assess tissue and vital organ perfusion and to diagnose injury from trauma, find the source of infection with sepsis, or identify the cause of cardiac failure. A chest radiograph, electrocardiogram, finger-stick glucose measurement,
complete blood count (CBC), urinalysis, serum electrolytes, and kidney and liver function tests are all indicated in the ED assessment. Arterial blood gases are ordered for a base deficit calculation and to correlate arterial oxygen partial pressure (Pao₂) with that measured by pulse oximetry, when the latter is deemed unreliable. Serum lactate measurement should be performed as early as possible in patients with suspected shock. Either venous or arterial lactate concentrations can be used. If peripheral venous lactate is used, time, storage temperature, and tourniquet use have no significant effect on in vitro lactate production by erythrocytes if the measurement is done within 15 minutes after the sample is obtained. Some EDs have bedside ultrasound capability, and both cardiac and abdominal scanning can be rapidly performed at the bedside to screen for inadequate central venous volume, occult hemothorax, or aneurysm, peritonitis, abdominal aortic aneurysm, left ventricular failure, and cardiac tamponade. A systematic ultrasound protocol can significantly improve the physician’s ability to accurately diagnose the cause of undifferentiated shock in ED patients, and the finding of hyperdynamic left ventricular function in patients with undifferentiated shock strongly suggests sepsis as the cause.

Consensus definitions of shock show the spectrum of hypoperfusion for the following three common causes of shock:

1. **Septic shock**
   - The American College of Chest Physicians, European Society of Intensive Care Medicine, Society for Critical Care Medicine, American Thoracic Society, and the Surgical Infection Society developed international consensus definitions for distinguishing septic shock from its precursor conditions, the systemic inflammatory response syndrome (SIRS), sepsis, and severe sepsis. Although this particular consensus requires persistent hypotension after fluid resuscitation to strictly define septic shock, initiation of treatment for empirically diagnosed severe sepsis or septic shock should not await the onset of hypotension.

2. **Hemorrhagic shock**
   - The American College of Surgeons has divided hemorrhagic shock into four stages, depending on the clinical evidence of hemorrhagic shock: simple hemorrhage, hemorrhagic shock, and hemorrhagic shock with hypoperfusion.

3. **Cardiogenic shock**
   - Cardiac failure plus four criteria listed in Box 4-2.
the severity of blood loss and the physiologic response to this loss, but such arbitrary divisions are of little value. A more useful approach defines hemorrhagic shock as being present when systemic hypoperfusion manifests as lactic acidosis with organ dysfunction.

3. Cardiogenic shock. Cardiogenic shock should be thought to be present whenever cardiac failure (ischemic, toxic, or obstructive) causes systemic hypoperfusion that manifests as lactic acidosis with organ dysfunction.

### MANAGEMENT

#### Monitoring Perfusion Status

In the effort to resuscitate a patient with circulatory shock, the clinician must follow specific indices of systemic perfusion and organ function to know if the resuscitation effort is working. In all patients with shock, circulation must be monitored by continuous electrocardiography and pulse oximetry. Cuff sphygmomanometer measurement of BP should be performed frequently during resuscitation. Because cuff sphygmomanometer measurement may be inaccurate in severe hypotensive states, the use of an arterial pressure monitoring line should be considered, especially if vasoactive medications are being administered. BP and HR correlate poorly with cardiac index (CI) in shock and often underestimate the severity of systemic hypoperfusion. Moreover, children with hypovolemic shock frequently demonstrate a normal BP until they rapidly deteriorate. Urine output should be measured as an index of vital organ perfusion (about 1 mL/kg/hr in persons without renal disease). A downward trend of the serum lactate concentration or upward trend of the base deficit, when observed with improving vital signs and urine output, is a reliable gauge of the adequacy of resuscitation and prognosis in shock from any cause. A rising lactate concentration (or refractory hypotension with worsening base deficit) despite ongoing resuscitation is a portent of imminent death, and vigorous resuscitation efforts or specific procedural intervention should be instituted.

Most patients with shock can be fully resuscitated with peripheral venous access established with two catheters of at least a size 18 gauge. Monitoring of central venous pressure (CVP) as part of a goal-directed resuscitation may improve outcome in patients with septic shock. Patients with cardiac failure or renal failure may benefit from closer measurement of the CVP and insertion of a central venous catheter. An 8.5-French catheter (Cordis Sheath) allows for accurate measurement of the CVP and insertion of a pulmonary artery catheter or other monitoring device if needed. In children a 3- or 5-French bilateral catheter can be placed in the femoral vein with few complications. To reduce the potential for limb damage from extravasation from a peripheral IV, vasoactive medications are optimally administered through a central venous catheter. If vasoactive medications are administered, additional peripheral intravenous catheters are required for infusion of crystalloid and other treatments. Many patients with renal disease or cancer have indwelling catheters. In patients with empirical criteria for shock, this catheter should be used for IV access, unless satisfactory access has already been established at other anatomic sites. In EDs where the standard practice is not to use these ports at the request of other physicians, a specific hospital policy and training session should be developed to make an exception in the case of circulatory shock. In general, failure to administer fluids rapidly and in sufficient quantity outweighs considerations about preservation of the line for future therapy.

#### Quantitative Resuscitation

Quantitative resuscitation (also called goal-directed therapy, goal-oriented resuscitation, or hemodynamic optimization) was first described in 1988 and refers to the practice of resuscitating patients to predefined physiologic endpoints indicating that systemic perfusion and vital organ function have been restored. Since that time many studies have evaluated the efficacy of such a therapeutic approach to shock, and a meta-analysis of these studies confirms its benefit for reducing mortality rates. For many years in the intensive care unit (ICU), physicians have relied on the use of the pulmonary artery catheter (PAC) to help optimize left ventricular filling indices. At present the use of the PAC remains controversial. In the last 5 years, five randomized controlled trials investigating the management of critically ill patients with a PAC have been published. None have found a benefit in terms of survival or length of stay. Insufficient data have been published to support the use or avoidance of PACs in ED populations; however, extrapolating from ICU studies, PACs have no role in the management of shock in the ED.

Several alternative methods to the PAC have been proposed as endpoints to resuscitation in the ED. The lactate clearance index refers to serial measurements of venous or arterial lactate. Lactate clearance involves measuring the blood lactate concentration at two or more times. If the lactate concentration has not decreased by 10% two hours after resuscitation has begun, additional steps must be undertaken to improve systemic perfusion. Resuscitation should continue until the lactate concentration drops below 2 mM/L. Clinical trials are presently investigating the utility of lactate clearance as an endpoint of resuscitation, which will have ramifications for the increasing use of point-of-care lactate testing platforms in the ED.

**Mixed venous oxygen saturation (SvO₂)** measurements reflect the balance between oxygen delivery and oxygen consumption. Previous studies have suggested that the SvO₂ can be used as a surrogate to CI when targeting normalization of endpoints (SvO₂ = 65% or CI 2.5–3.5 L/min/m²) for therapeutic intervention in critically ill patients. Although SvO₂ requires the use of a PAC, the central venous oxygen saturation (ScvO₂) drawn from the central circulation has been shown to closely parallel the SvO₂, especially when tracking changes or trends in the values.

Early quantitative resuscitation, which incorporates multiple indices of circulatory and oxygenation status, was shown in one randomized controlled trial to significantly reduce mortality and morbidity rates in ED patients with severe sepsis or septic shock. Patients are resuscitated within the first 6 hours of care to achieve normalization of CVP and mean BP and to maintain a ScvO₂ greater than or equal to 70% (Fig. 4-2). The decrease in mortality rate from this new treatment strategy, termed early goal-directed therapy, has been found effective in smaller prospective before-and-after studies of patients with sepsis. Large multicenter validation of this resuscitation strategy in sepsis is underway. However, it has not been tested in other causes of shock but shows the value of using defined physiologic endpoints to measure systemic perfusion during resuscitation from shock in the ED. This approach also further substantiates the importance of the first 6 hours of resuscitation.

#### Ventilation

Rapid sequence intubation is the preferred method of airway control in most patients with shock (see Chapter 1). Intubation
Figure 4-2. Flow diagram outlining the protocol for quantitative resuscitation when treating patients with severe sepsis or septic shock. This protocol outlines specific hemodynamic and physiologic parameters the clinician should seek to achieve within the first 6 hours of care. This protocol is focused on resuscitation and should be used in conjunction with standard clinical care for patients with suspected infection, such as appropriate diagnostic studies to determine the focus of infection and appropriate antimicrobial agents to treat the infection. CVP, central venous pressure; MAP, mean arterial pressure; ScvO₂, central venous oxygen saturation. (Redrawn from Rivers E, et al: Early goal-directed therapy in the treatment of severe sepsis and septic shock. N Engl J Med 345:1368, 2001.)

Box 4-4 presents the general treatment approach for the four common causes of shock. Hemorrhagic Shock

Ensure adequate ventilation/oxygenation
Provide immediate control of hemorrhage, when possible (e.g., traction for long bone fractures, direct pressure)
Initiate judicious infusion of isotonic crystalloid solution (10–20 mL/kg)
With evidence of poor organ perfusion and 30-minute anticipated delay to hemorrhage control, begin packed red blood cell (PRBC) infusion (5–10 mL/kg)
With suspected central nervous system trauma or Glasgow Coma Scale score <9, immediate PRBC transfusion may be preferable as initial resuscitation fluid
Treat coincident dysrhythmias (e.g., atrial fibrillation with synchronized cardioversion)

Cardiogenic Shock

Ameliorate increased work of breathing; provide oxygen and positive end-expiratory pressure (PEEP) for pulmonary edema
Begin vasopressor or inotropic support; norepinephrine (0.5 μg/min) and dobutamine (5 μg/kg/min) are common empirical agents
Seek to reverse the insult (e.g., initiate thrombolysis, arrange percutaneous transluminal angioplasty)
Consider intra-aortic balloon pump counterpulsation for refractory shock

Septic Shock

Ensure adequate oxygenation; remove work of breathing
Administer 20 mL/kg of crystalloid or 5 mL/kg of colloid, and titrate infusion to adequate central venous pressure and urine output
Begin antimicrobial therapy; attempt surgical drainage or débridement
Begin PRBC infusion for hemoglobin < 8 g/dL
If volume restoration fails to improve organ perfusion, begin vasopressor support; initial choice includes dopamine, infused at 5–15 μg/kg/min, or norepinephrine, infused at 0.5 μg/min

Volume Replacement

The next imperative in shock is to decide when “the tank is full.” The goal in volume replacement is slightly elevated left ventricular end-diastolic volume, which is a difficult measurement to make in the ED. The CVP is most often used to estimate right ventricular filling pressure and is used in some quantitative resuscitation algorithms. Because both ventricles tend to stiffen during shock, a high CVP (10–15 cm H₂O) is often needed to produce adequate filling volume. It is a long way, however, from the CVP measurement to actual knowledge of left ventricular end-diastolic volume; a presumed adequate CVP must be substantiated by increases in urine output and BP and decreasing lactate concentrations.

Treating Specific Causes

Box 4-4 presents the general treatment approach for the four common causes of shock.
Standard treatment for hemorrhagic shock consists of rapidly infusing several liters of isotonic crystalloid in adults or three successive 20-mL/kg boluses in children. Colloids, including albumin and hydroxethyl hetastarch (Hespans), can be used as well as but at considerable increase in cost and without effect on morbidity or mortality rates. Colloids offer the theoretic advantage of a high osmotic pressure, which should help to maintain a normal intravascular volume after retransfusion from hemorrhage. If criteria for shock persist despite crystalloid infusion (see Box 4-2), packed red blood cells (PRBCs) should be infused (1–2 units in adults or 5–10 mL/kg in children). Type-specific blood should be used when the clinical scenario permits, but uncrossmatched blood should be used at the earliest opportunity for patients with arterial hypotension and uncontrolled hemorrhage. O-negative blood is used in women of childbearing age and O-positive blood in all others (see Chapter 5). Substantial evidence supports the use of leukodepleted blood, which has been filtered to remove donor leukocytes. Leukodepleted blood is used in countries outside the United States because it produces less retransfusion-related organ damage.

The infusion of hemoglobin-based oxygen carriers as alternatives to PRBCs for resuscitation of hemorrhagic shock have been extensively studied. In a large randomized controlled trial, diaspirin cross-linked hemoglobin, a purified and chemically modified human hemoglobin substrate, was compared with crystalloid for initial resuscitation in the critically injured, and its use resulted in a higher mortality rate at interim analysis, resulting in termination of the trial. Other artificial hemoglobin substitutes may be available in the future but at present show no benefit over PRBCs.

Recent studies have endorsed the concept of either delayed resuscitation or hypotensive resuscitation for hemorrhagic shock. This is discussed in Chapters 34, 42, and 43. Controlling hemorrhage remains the cornerstone of treating hemorrhagic shock, and evidence continues to support immediate surgery when direct vascular control cannot otherwise be obtained (see Chapter 34).

**Septic Shock**

Septic shock begins as an infectious nidus, which triggers a domino effect of cellular, microvascular, hematologic, and cardiovascular dysfunction. Treatment begins by establishing adequate ventilation to correct hypoxia and acidosis and to reduce systemic oxygen consumption and left ventricular work. This often requires endotracheal intubation and sedation for mechanical ventilation. The controversy regarding the use of etomidate in patients with septic shock is discussed in Chapter 1.

The second goal is to achieve adequate ventricular filling. The choice of fluids in treating septic shock is probably less important than meticulous monitoring for adequate tissue perfusion. However, choices for fluid resuscitation should involve consideration of availability and the cost-benefit ratio. Initial volume replacement should include rapid infusion of 20 to 25 mL/kg of crystalloid. If hypoperfusion is persistent, 5- to 10-mL/kg boluses of a colloid should be considered. Blood should be transfused in the ED to restore hematocrit to at least 30 to 35%.

The third directive is eradication of the infection with antimicrobial therapy and, where necessary, surgical drainage. A recent study reported that in adult patients with septic shock, effective antimicrobial administration within the first hour of documented hypotension was associated with increased survival to hospital discharge and that each hour delay in antimicrobial administration over the first 6 hours after recognition was associated with an average decrease in survival of 7.6% per hour. The choice of antimicrobial agent can be directed by clinician experience and institutional minimal infective concentration (MIC) data. When no focus can be found in septic shock, a semisynthetic penicillin with a β-lactamase inhibitor, in combination with an aminoglycoside plus vancomycin is a rational empirical choice. When neutropenia is suspected in a patient with sepsis syndrome, the progression to refractory, fatal septic shock can be cataclysmic. Neutropenia is suggested in patients who have recently undergone chemotherapy. Chemotherapy patients with sepsis represent a special challenge because the pathophysiology may be complicated by anemia, thrombocytopenia, dehydration from vomiting, and the effect of adjunctive steroid therapy. Chemotherapy patients often have indwelling catheters, which predisposes them to more unusual causes of sepsis, including gram-positive bacteria and fungi (see Chapter 143).

Septic shock refractory to volume restoration (urine output or BP remains low; lactate increases) requires vasopressor support. The primary goal of vasopressor support is to increase cardiac output and oxygen delivery to vital organs. Norepinephrine (0.5–30 μg/min) or dopamine (5–20 μg/kg/min) are the first-choice vasopressors for correcting hypotension in septic shock. Norepinephrine is more potent than dopamine and thus may be more effective at reversing hypotension; however, dopamine may be preferred in the setting of inadequate systolic heart function. Dobutamine may also be used with norepinephrine to increase cardiac output and maintain adequate oxygen delivery. A recent multicenter randomized controlled trial of 330 subjects reported that, when simultaneous blood pressure and inotropic support were necessary, there is not a difference in safety or efficacy between epinephrine (0.2 μg/kg/min starting dose) alone and norepinephrine plus dobutamine. Many other studies of different vasopressor regimens are ongoing; however, to date there is no definitive evidence to clearly support the use of one vasopressor over another in septic shock.

Drotrecogin alfa activated (or activated protein C), a recombinant human activated protein with anti-inflammatory, anti-thrombotic, and profibrinolytic properties, has been investigated in large multicenter trials for the treatment of patients with systemic inflammation and organ failure from acute infection. The institution of activated protein C therapy is not part of the routine ED management of sepsis as there is a large window of time for treatment initiation (within 24 hours of meeting criteria). If this therapy is considered, consultation with the ICU physician who will assume care of the patient is recommended because the therapy is continued for 96 hours.

The use of corticosteroids in the treatment of sepsis and septic shock has been investigated with mixed results. The results of two large randomized controlled trials confirm that there is no role for high-dose, short-course corticosteroid therapy in septic shock. Recently, two large multicenter randomized trials of low-dose hydrocortisone treatment failed to show survival benefit among all patients with septic shock. One of the studies did show a survival benefit to use of low-dose hydrocortisone among patients who did not adequately respond to a corticotropin stimulation test; however, the larger study did not find this survival benefit. Most current guidelines recommend that low-dose hydrocortisone should only be administered to patients receiving chronic steroid replacement and in patients with refractory shock despite adequate fluid and vasopressor support, and corticotropin stimulation testing is no longer considered of value.
Cardiogenic Shock

The immediate treatment of cardiogenic shock focuses on improving myocardial contractility and pump function. Cardiogenic shock is traditionally defined as the combination of systemic signs of hypoperfusion with arterial systolic BP less than 90 mm Hg (or 30% below a known baseline). If the work of breathing is tiring the patient, if severe pulmonary edema is causing significant hypoxemia, or if respiratory failure is imminent, intubation and mechanical ventilation should be initiated, followed by emergent treatment of bradydysrhythmias or tachydysrhythmias and inotropic support. Barbiturates are not recommended for sedation or anxiety in the intubated patient, because they may have exaggerated negative inotropic effects. Cautious use of benzodiazepines, supplemented by fentanyl for analgesia, is the best approach. Improving perfusion often ameliorates the anxiety and restlessness that accompanies shock states. Etomidate and ketamine have the least risk for hemodynamic compromise and should be used (but in reduced doses) for intubation, accompanied by a full dose of succinylcholine. Prior to administration of vasoactive medications, if hypovolemia is present, it should be corrected by infusing crystalloid or blood products. To improve myocardial contractility, vasopressors or inotropic agents should be administered. The choice of which agent to use depends on signs and symptoms and on the systolic blood pressure (SBP). If the SBP is less than 70 mm Hg and the signs and symptoms of shock are present, norepinephrine is the agent of choice. If the SBP is between 70 and 100 mm Hg and the signs and symptoms of shock are present, dopamine should be used. However, if the SBP is 70 to 100 mm Hg and there are no signs or symptoms of shock, dobutamine is the agent of choice. All of these agents should be started at the same doses used for septic shock. For refractory hypotension and shock, amrinone or milrinone may improve cardiac output, although no empirical evidence is available to support their routine use. Amrinone and milrinone are biperidin derivatives that increase cyclic adenosine monophosphate (cAMP) by inhibiting phosphodiesterase (complex F-III). A loading dose of 0.75 mg/kg for amrinone or 50 μg/kg for milrinone is necessary, followed by a titrated constant infusion for either drug (5–10 μg/kg/min for amrinone and 0.5 μg/kg/min for milrinone).

When pharmacologic support fails to improve indices of perfusion, the next step is to initiate intra-aortic balloon pump counterpulsation (IABPC). This requires the facilities and personnel of a high-level ICU or coronary care unit (CCU). Controlled trials have shown IABPC to improve short-term survival, improve post-thrombolytic patency rates, and reduce stroke morbidity. IABPC increases cardiac output by a mean of 30% in refractory cardiogenic shock and can prolong survival until interventional procedures can be performed. IABPC may be contraindicated in patients with aortic insufficiency or severe peripheral vascular disease.

The dismal outcome of cardiogenic shock complicating acute myocardial infarction (MI) has been improved in recent years. Evidence suggests that emergent revascularization is not superior to medical management in reducing mortality rates in the short term; however, significant improvements in general mortality rates are seen at both 6 months and 1 year (see Chapter 77). At present the management of acute MI with cardiogenic shock proceeds as follows and constitutes optimal therapy: (1) ensure adequate ventilation and oxygenation, (2) treat emergent dysrhythmias, (3) initiate vasopressor/inotropic support, (4) administer aspirin if the patient is not allergic, and (5), heparin anticoagulation and arrangement for emergent percutaneous coronary intervention.

**PERSPECTIVE**

The era of modern blood transfusion began in the early 1900s with discovery of the ABO red cell antigen system. By World War I it was known that adding citrate enabled the storage of anticoagulated blood. Blood banking in the United States began during the 1930s. Energetic pioneers such as John Lundy of the Mayo Clinic gained a wealth of clinical experience, prompting dissemination of expert-based advice, such as Lundy’s recommendation that blood transfusion was appropriate when a patient’s hemoglobin (Hgb) was less than 10 g/dL or when a patient lost more than 15% of circulating blood volume. These recommendations were not, however, based on rigorous controlled trials. Rapid expansion of blood banking occurred after World War II, and in subsequent decades research focused on such critical issues as prolonging the storage life of blood products, component therapy, and reducing the risk of transfusion reactions and transfusion-related infections.1,2

More recently, at a time when nearly 14 million units of packed red blood cells (PRBCs) are transfused yearly in the United States, attention has turned toward evaluating the efficacy of more restrictive transfusion policies, rethinking the overall risk-benefit ratio of blood products, and developing bloodless alternatives.1,3-7

**PATHOPHYSIOLOGIC PRINCIPLES**

**Blood Banking**

Blood centers, such as those of the American Red Cross and America’s Blood Centers, process more than 90% of the units collected in the United States. Traditional allogenic donation methods still predominate, but increasing use is being made of red cell apheresis technology, by which red cells are separated from the blood at the time of collection, with the rest returned to circulation. This allows collection of about two transfusable units during a single donation.

Blood collection bags contain an anticoagulant-preservative of citrate, phosphate, dextrose, and adenine (CPDA-1), ensuring a shelf life (viability of at least 70% of the RBCs 24 hours after infusion) of 35 days and hematocrit of 70 to 80% for PRBCs.8 Additive solutions (Adsol, Nutricel, Optisol) provide additional nutrients, extending maximum storage to 42 days and lowering viscosity, which makes infusion easier.9,10

Storage impairs red cell function. Transfused blood delivers oxygen to the tissues less efficiently. Even though blood is refrigerated at 1 to 6°C (usually 4°C), cell metabolism continues and changes occur (collectively referred to as the *storage lesion*). Documented alterations are numerous and include a decrease in pH and in the level of 2,3-diphosphoglycerate (2,3-DPG). In addition, the deformability of RBCs makes them, over time, more spherical and rigid, thereby increasing resistance to capillary flow. With time, many of these changes are reversed in vivo. The decrease in 2,3-DPG, for example, results in a left shift in the hemoglobin-oxygen dissociation curve (less oxygen is released at a given partial pressure of oxygen [P\text{O}_2]), but the ability to synthesize 2,3-DPG is regained over the first 24 hours after transfusion.10 The relationship between overall oxygen transport and oxygen delivery to tissues is complex. Depletion of S-nitrosohemoglobin during storage alters oxygen-dependent regulation of microcirculatory blood flow (“hypoxic vasodilation”).11 There is ongoing debate about whether and when these and other changes are clinically significant, and how they might be overcome.12-16

Additional well-established changes include cell leakage of potassium, although the amount (= 6 mEq/L)17 is readily tolerated by most otherwise healthy patients. PRBCs contain essentially no functional platelets or granulocytes.

**Blood Typing**

A basic knowledge of compatibility testing allows emergency physicians to order blood bank products and services appropriately. Identified red blood cell (RBC) antigens include the ABO and related carbohydrate antigens (H, P, I, and Lewis), the 48 Rh system antigens, and more than 200 non-ABO/Rh antigens. When a clinician anticipates that transfusion might be indicated, a “type and screen” can be ordered, and a blood specimen from the patient is sent for the following tests: ABO grouping, Rh typing, and an antibody screen for unexpected (non-ABO/Rh) antibodies. Completion of these steps speeds the delivery of crossmatched blood if it is subsequently required.

ABO incompatibility results in acute hemolysis, the most serious transfusion reaction. ABO grouping requires that the recipient’s red cells be tested with anti-A and anti-B serum, and that their serum be tested with A and B red cells.8 Patients form antibodies at about 6 months of age against the A and B antigens they lack. Those with type AB blood form no ABO group antibodies. Patients who are type O have antibodies against both. The major clinically
Significant Rh antigen is the D antigen. Rh typing can usually be determined by adding a commercial reagent (anti-D) to recipient RBCs.

The antibody screen identifies clinically significant "unexpected antibodies" in the patient’s serum. These antibodies form when a patient responds to a foreign RBC antigen, usually due to prior exposure, such as with allogenic transfusion, pregnancy, or organ transplant. The antibody screen is performed by mixing commercial RBC reagents (mixtures of red cells expressing clinically significant antigens) with the patient’s serum. The incidence of these unexpected antibodies in the general population is low (<1–2%), but a positive screen mandates further compatibility testing.10,17

The type and screen allows quicker selection of appropriate banked blood for complete crossmatch if a transfusion is ordered. Ideally, blood identical to the patient’s own ABO and Rh group is used. Local blood supplies, however, might dictate that a nonidentical, but compatible, unit be used. Patients with blood group AB, for example, can receive blood from any of the ABO groups. Men, and women beyond childbearing age, who are Rh-negative and have no preformed Rh (anti-D) antibodies may receive either Rh+ or Rh− blood. When a blood transfusion is ordered, a formal crossmatch is done by mixing recipient serum with donor RBCs as a final compatibility test prior to transfusion. This can be done using a Coombs test (with serum incubated to 37°C), or the more rapid “immediate spin crossmatch” at room temperature, which will detect only ABO incompatibility. The more thorough Coombs’ test can detect incompatibilities that were missed with the antibody screen.17

Special Clinical Circumstances

To select the most appropriate blood product in the emergency setting, clinicians must consider the patient’s hemodynamic stability and the amount of time available to intervene.17

Universal Donor Group O

Universal (group O) blood is used when RBCs must be given at once to hemorrhaging, unstable patients. Premenopausal females (adults and children) need group O Rh-negative blood, whereas men and all other women may receive O Rh-positive blood, which is more common. Conversely, the “universal” type for fresh frozen plasma (FFP) is type AB, since it contains no antibodies to either A or B antigens.

If the patient’s condition can be initially stabilized with crystalloid infusion, type-specific blood (using ABO and Rh testing) should be available within 15 minutes of receiving a sample of the patient’s blood.

An antibody screen and immediate spin crossmatch take approximately 45 to 60 minutes. The recipient’s serum is screened for unexpected antibodies as described earlier. An “immediate spin crossmatch” is then performed at room temperature if the antibody screen is negative.

If the antibody screen is positive, however, the antibody is identified using more elaborate procedures, and a complete crossmatch (using a Coombs test with incubated serum) is required. This process can take up to several hours.17

Massive Transfusion

Abnormalities from massive transfusion are rarely seen during a patient’s initial resuscitation in the emergency department, but the physician should be aware of potential problems. Massive transfusion has been defined as transfusion equiva-
controlled, uncontrolled), can be supplemented by laboratory evaluation of Hgb, hematocrit, platelets, and clotting functions.

A review of relevant literature underscores the difficulty of making firm recommendations. Only recently have randomized controlled trials investigated the efficacy of various transfusion triggers in the critical care and surgical setting. The largest randomized trial in adult patients to date, the TRICC (Transfusion Requirements in Critical Care) trial, demonstrated that in the critical care setting, a transfusion threshold of 7 g/dL was as safe as a threshold of 10 g/dL, although subgroup analysis generated some concern that patients with ischemic heart disease may benefit from a higher transfusion threshold. In a large, retrospective analysis of patients hospitalized with acute myocardial infarction, anemia appeared to raise the risk of death, and transfusion for a hematocrit of 33% or less improved overall mortality rates. It is debatable, however, whether these results can be generalized to the emergency department setting. Further research is urgently needed. The list of known and suspected risks associated with transfusion, on the other hand, is long and growing. Recent concerns include Transfusion Related Acute Lung Injury (TRALI) and immune modulation. As a result, recent guidelines generally recommend a “restrictive strategy” for most patients, utilizing transfusion triggers more stringent than those traditionally followed. Recommendations for the use of FFP likewise have long been more expert-based than evidence-based.

Whole Blood
Whole blood is not as economical as component therapy, although there has recently been renewed interest in the benefits of using fresh whole blood in military field hospitals. In the United States it is rarely used.

Packed Red Blood Cells
PRBCs are given to improve oxygen delivery to tissues at the microvascular level. Concerns regarding efficacy were discussed earlier; absent further research, the recommendations of the American Society of Anesthesiologists seem reasonable: transfusion is rarely needed with a Hgb concentration greater than 10 g/dL and almost always needed when the Hgb is less than 6 g/dL. Patients with a Hgb between 6 and 10 mg/dL require careful clinical judgment. Ischemic heart disease may render patients more intolerant of anemia, although more research is needed to clarify whether transfusion benefits these patients. Lastly, most emergency physicians would still transfuse a patient with ongoing hemorrhage and unstable vital signs despite adequate fluid resuscitation, and would occasionally consider withholding transfusion for Hgb levels even lower than 6 g/dL in a young, healthy, asymptomatic patient without ongoing hemorrhage.

Artificial Oxygen Carriers
Research into both hemoglobin-based oxygen carriers and perfluorocarbon emulsions is ongoing, but as yet none are approved for general clinical use in the United States. Several problems remain unsolved. Hemoglobin-based carriers, for example, have been found to cause vasoconstriction through nitric oxide (NO) scavenging, endothelin release, and peripheral alpha-adrenergic receptor sensitization. Perfluorocarbon emulsions require relatively high partial pressure of oxygen (Po2) levels. When used clinically, pure oxygen is usually administered to patients.

Fresh Frozen Plasma
Current practice dictates that FFP be given to patients with evidence of coagulopathy (international normalized ratio [INR] >1.5–2.0) who are either actively bleeding (absolute indication) or require an invasive procedure (relative indication). Most clinicians consider active bleeding to include clinically significant hemorrhage, not minor degrees of oozing. If a specific factor deficiency is identified (e.g., hemophilia), targeted replacement of that factor, if available, is more practical. FFP should not be used for volume expansion.

Platelets
Platelet transfusion is indicated prophylactically when the count is less than 10,000/mL, and this includes a margin of safety, as it appears that hemostasis is well-maintained even at counts of 5000/mL. Platelet counts of 40,000 to 50,000/mL are sufficient to perform invasive procedures. Platelets have traditionally been given to adults in a dose of 6 U of platelet concentrate (i.e., a “six-pack” of platelets), which typically raises the platelet count about 40,000 to 60,000/mL. This practice is not, however, evidence-based. Because hemostasis is maintained with platelet counts as low as 5000/mL, it seems likely that smaller, more frequent platelet transfusions should be equally efficacious, but more cost-effective in hospitalized patients. This may be impractical, of course, in outpatients. An ongoing randomized trial addresses this issue by assigning patients to low-, medium-, and high-dose platelet regimens. Lastly, if immune-mediated consumption is the cause of thrombocytopenia, transfusion is generally ineffective.

Autotransfusion
Autotransfusion may be used in the emergency setting in the event of severe chest trauma. This strategy has numerous advantages: immediate availability, blood compatibility, elimination of patient-to-patient disease transmission, avoidance of the storage lesion, less risk of circulatory overload, and fewer direct complications (e.g., hyperkalemia, hypothermia, hypocalcemia, and metabolic acidosis). There is also greater acceptability to some patients whose religious convictions prohibit transfusions. Widespread use has not occurred, however, because of the limited number of appropriate trauma patients, the training required to operate the equipment, and the time required for equipment setup.

Therapeutic Modalities
Packed Red Blood Cells
In acute hemorrhage, PRBCs are used to supplement initial crystalloid replacement. In an average adult, 1 U of PRBCs increases the Hgb by about 1 g/dL or the hematocrit by about 3%. A similar increase in pediatric patients is obtained by administering 3 mL/kg. PRBCs are run through a filter with a large-bore intravenous line with normal saline. Lactated Ringer’s solution can lead to clotting secondary to the added calcium, and hemolysis may result with a hypotonic solution. Medications should not be added to the unit or pushed through the transfusion line unless it has been thoroughly flushed. Most transfusions are given over 60 to 90 minutes (not longer than 4 hours). Unused blood should be returned promptly to the blood bank because any units unrefrigerated for more than 30 minutes are discarded.
A unit of FFP typically has a volume of 200 to 250 mL, is ABO compatible, and is given through blood tubing within 2 to 6 hours of thawing. It contains all clotting factors. One unit of activity for any coagulation factor is equal to the clotting activity found in 1 mL of FFP. It should be given in doses calculated to achieve a minimum of 30% of plasma factor concentration, traditionally calculated as 10 to 15 mL/kg of FFP. When used for the urgent reversal of warfarin anticoagulation, 5 to 8 mL/kg of FFP is considered sufficient. Recent research, however, has questioned this, and indicates that screening tests such as INR and activated partial thromboplastin time (aPTT) do not correlate well with clinical risk of bleeding, and large amounts of FFP (possibly as high as 30 mL/kg) may be needed to raise factor levels adequately to achieve hemostasis. The need to correct the INR for invasive procedures such as central line placement has also been questioned.

Platelets

Crossmatch is unnecessary, but Rh-negative patients should receive Rh-negative platelets because there may be enough cells in the platelet concentrate to cause Rh sensitization. In adults the traditional dose has been 4 to 6 U (a “six pack” of platelets), and in children it is 1 U/10 kg body weight. As noted earlier, however, consider giving smaller, more frequent transfusions in hospitalized patients. In frequently transfused patients it is often desirable to reduce human leukocyte antigen (HLA) sensitization. The use of leukoreduced, HLA-matched, cellular products decreases the risk of HLA antibody-induced immune destruction.

OUTCOMES

Adverse effects of RBC transfusion can be divided into immune-mediated and non-immune-mediated categories, as well as acute, delayed, and chronic effects.

Immune-Mediated Adverse Effects

Acute

**Intravascular Hemolytic Transfusion Reaction.** Intravascular hemolytic transfusion reaction is the most serious transfusion reaction. It is usually the result of ABO incompatibility, most often due to error. The resulting antigen-antibody reaction leads to the intravascular destruction of transfused red cells, producing hemoglobinemia and hemoglobinuria. The onset of symptoms is immediate and may include fever, chills, headache, nausea, vomiting, a sensation of chest restriction, severe joint or low back pain, and a burning sensation at the site of the infusion. Clinical effects can include hypotension, DIC, and acute tubular necrosis. Treatment includes stopping the transfusion immediately, replacing all old tubing with new, and initiating vigorous crystalloid fluid therapy. Diuretic therapy should be used to maintain urine output at 1 to 2 mL/kg/hr. Pressor agents may be needed to support the blood pressure and protect the kidneys. Blood and urine specimens should be sent to the laboratory, as well as the remainder of the transfusion and the blood tubing. Detecting free Hgb (blood and urine) and a positive Coombs test on post-transfusion, but not pretransfusion specimens confirms the diagnosis.

**Febrile Transfusion Reaction.** This is the most common and least serious transfusion reaction and is defined as a 1 °C temperature elevation associated with transfusion that has no other medical explanation. Reactions are believed to result from antileukocyte antibodies, most commonly as a result of prior transfusion. Treatment is symptomatic with an analgesic-antipyrretic and an antihistamine. The use of leukoreduced RBCs can decrease, but not eliminate, the risk of this reaction. If a febrile reaction occurs in a first-time transfusion, it should be treated in the same way as an intravascular hemolytic reaction until proven otherwise.

**Allergic Reactions (Urticaria to Anaphylaxis).** Urticaria, or hives, may occur during a transfusion without other signs or symptoms and with no serious sequelae. It is generally attributed to an allergic, antibody-mediated response to a donor’s plasma proteins. The transfusion does not need to be stopped, and treatment with an antihistamine is usually sufficient. If the patient has a known history of urticaria, the antihistamine should be administered before the transfusion. Occasionally, full anaphylaxis may be caused by an anti-immunoglobulin A (IgA) reaction to IgA in the donor’s blood components. The patient is likely to have a genetic IgA deficiency and display hypotension, respiratory and gastrointestinal symptoms, but no fever. Treatment is with epinephrine and corticosteroids. Future transfusions should be with washed RBCs, and plasma products should be from other IgA-deficient individuals.

**Transfusion-Related Acute Lung Injury.** TRALI, now considered the leading cause of transfusion-related mortality, presents abruptly during, or within 6 hours of, the transfusion of plasma-containing blood products. These include PRBCs, FFP, platelets, and cryoprecipitate. The initial clinical presentation is that of a noncardiogenic pulmonary edema, with dyspnea, hypoxemia, and bilateral infiltrates on chest radiograph. Fever, hypotension, and transient leukopenia may also be seen. Other causes of acute lung injury should be ruled out. The underlying pathophysiologic mechanism is a subject of continuing debate and could involve multiple insults. Proposed theories include a reaction between transfused antibodies and granulocytes in the recipient, as well as the effects of biologically active factors that accumulate in stored blood such as cytokines and lipids. One strategy suggested for reducing TRALI has been to use only male donors for plasma in order to avoid allotypic leukocyte antibodies which can occur in women as a result of prior pregnancies.

Appropriate treatment consists of stopping the transfusion, notifying the blood bank, and providing respiratory support, which may include intubation and mechanical ventilation. It is safe to continue transfusion of blood products from a different donor, if necessary. Complete resolution is typically seen within 48 to 96 hours. Overall prognosis is better than would be expected with many other causes of acute lung injury, with a reported mortality rate of 6% in one series. Survivors rarely show long-term adverse effects.

Delayed

**Extravascular Hemolytic Transfusion Reaction.** These result from a non-ABO-mediated immune reaction, most often due to an anamnestic response in a patient previously sensitized to red cell antigens by transfusion, pregnancy, or transplant. This prior exposure may result in antibody levels that are too low to detect with the antibody screen. Following repeat exposure from transfusion, however, antibody levels rise, and extravascular hemolysis occurs days to weeks later. Less commonly, primary alloimmunization can occur after transfusion. The patient may have fever, anemia, and jaundice. Symptoms are not usually severe. Rare cases of oliguria or DIC can occur, however. Because the hemolysis is extravascular, hemoglobinemia and hemoglobinuria are typically not present.

Many
cases are subclinical, but management may require monitoring of hematologic and renal labs, maintenance of urine output, and additional red cell transfusions. Care is needed for subsequent transfusions to provide antigen-negative blood, which can be discussed with the blood bank.

Transfusion-Associated Graft-Versus-Host Disease. This rare, but life-threatening, complication results when transfused lymphocytes proliferate and attack the recipient. Cell-mediated immunodeficiency puts the patient at risk, as does having an HLA type that is identical between donor and recipient (most often among first-degree relatives). Symptoms, which begin 3 to 30 days following transfusion, include fever, erythematous skin rash, diarrhea, elevated liver enzymes, and pancytopenia. The only effective treatment is bone marrow transplant, and most deaths result from coagulopathy or infection. Efforts are therefore directed at prevention by using gamma irradiation of all cellular components, which renders the donor lymphocytes incapable of proliferating. The use of leukocyte-poor components is also advocated. This condition should be kept in mind when considering transfusion in anemic leukemia or lymphoma, especially in patients who have recently received chemotherapy. Consultation with an oncologist prior to transfusion should be strongly considered in these complex cases.

Non-Immune-Mediated Adverse Effects

Acute

Circulatory Overload. Chronically anemic, normovolemic elderly patients are at greatest risk for developing congestive heart failure with the rapid infusion of blood. Taking 4 hours to infuse a unit and using diuretics (if needed) should prevent this complication.

Bacterial Contamination. Bacterial contamination, most commonly with Yersinia enterocolitica (which grows well in cool, iron-rich environments), occurs in fewer than 1 per million units of stored RBCs, but typically results in symptoms during the transfusion, and carries a 60% mortality rate. Risk is higher, however, with platelets, which are stored at a higher temperature, and may occur as frequently as 1 per 1000 to 2000 U. During or after the transfusion, the patient may develop rigors, vomiting, abdominal cramps, fever, shock, renal failure, and DIC. When a septic transfusion reaction is considered, vigorous resuscitative therapy and broad-spectrum antibiotics should be started and the transfusion stopped.

Other Effects. Although infrequent, the following complications can occur secondary to multiple-unit transfusions: hypocalcemia, hyperkalemia and acidosis, hypothermia, microembolization, and coagulopathies. Treatment is specific to the symptom and problem.

Chronic

Risk of Transmission-Transmitted Viruses. Improved techniques for selecting and testing blood donors have dramatically reduced the risk of viral transmission of disease by transfusion. The blood supply in the United States has never been safer. Current estimates for the risk of acquiring hepatitis C and HIV from transfusion are approaching 1 in 2 million. The risk of hepatitis B infection, however, remains closer to 1 in 200,000 to 500,000. Cytomegalovirus (CMV) can be transmitted by blood transfusion as well. Those at risk include recipients of allogeneic stem cell or solid-organ transplantation, and neonates. CMV-negative blood products should be considered in these patients. Recently, West Nile virus has emerged as a risk, although one that varies considerably by geography and season (as high as 1233 per million units in one metropolitan area during the epidemic of 2002). Transfusion-related infection with West Nile virus, however, has been virtually eliminated by the use of system-wide nucleic acid amplification testing.

PERSPECTIVE
Recognition of the dominant role of the brain in determining the quality of human life dates back to the dawn of recorded medical history. Until recently, however, medical efforts after cardiac arrest have focused exclusively on cardiac resuscitation. Recent advances in the understanding of the pathophysiologic mechanisms of brain ischemia have encouraged attention to cerebral resuscitation. This chapter reviews the pathophysiology of postischemic encephalopathy and discusses therapies for improving neurologic recovery after cardiac arrest.

PATHOPHYSIOLOGY
The human brain consists of 10 billion neurons, each with multiple connections to other cells, totaling an estimated 500 trillion synapses. Although the brain constitutes only 2% of body weight, it receives 15% of the body’s cardiac output and accounts for 20% of the body’s overall oxygen use because of its high metabolic activity. Although no mechanical or secretory work is performed by the brain, energy expenditures include the synthesis of cellular constituents (e.g., an estimated 2000 mitochondria are reproduced each day by each cell) and neurotransmitter substances, the axoplasmic transport of these substances, and the transmembrane pumping of ions.

When the brain is deprived of adequate blood flow, the resulting ischemia is characterized by a bewildering array of inter-related physiologic and cellular responses that ultimately result in neuronal cell death (Fig. 6-1). Although this complex cascade of events can be triggered by periods of ischemia lasting only a few minutes, the resulting neuronal death is usually delayed by hours or days. Furthermore, the biology of cerebral cell death after global cerebral ischemia follows (with slight variations) the pattern of delayed cerebral cell death that occurs during CPR and that may occur from cardiogenic shock preceding or subsequent to the period of cardiac arrest. Extensive clinical evidence on hospital discharge rates and neurologic recovery rates supports the concept first proposed nearly 100 years ago that success in resuscitation is inversely proportional to the duration of cardiac arrest. Although duration of arrest generally predicts outcome in the population of patients with sudden cardiac death, it cannot be used reliably to predict the outcome of individual patients. The epidemiology of neurologic outcome of survivors is described in detail in the following section and is influenced by patient comorbidity and other individual characteristics. Depending on their timing and severity, low-flow states, hypotension, or hypoxia preceding cardiac arrest may provide protective preconditioning or may increase the risk of poor neurologic outcome.

The efficacy of closed-chest CPR in generating adequate cerebral perfusion is somewhat controversial. Cardiac output during optimal standard closed-chest CPR has previously been estimated to be only 20 to 30% of normal, but more recent data suggest that higher cardiac outputs are possible in clinical practice. Experimental measurement of CBF during CPR has led to estimates ranging from 1 to 60% of prearrest CBF, depending on the experimental model and technique and on the duration of arrest. Furthermore, the CBF achieved with standard closed-chest CPR is inversely proportional to the duration of cardiac arrest preceding the initiation of CPR. Researchers have obtained 50% of normal (prearrest) CBF in animals when CPR was started within 2 minutes of the onset of ventricular fibrillation, but they obtained only 28% of normal CBF if the circulatory arrest persisted for 5 minutes before...
CPR was started. After 10 minutes of arrest, CBF was zero with standard CPR. Although some experimental work suggests that about 20% of normal CBF is necessary to maintain neuronal viability, the real issue is not the degree of biochemical, electric, or physiologic abnormality measured in animal experiments of brain ischemia, but whether functional recovery will occur. Approached from this perspective, clinical evidence overwhelmingly confirms the beneficial effects of CPR in terms of improvement in survival and neurologic recovery.

Considerable effort has been directed toward the investigation of improved CPR techniques that will prove to be even more effective for longer periods (see Chapter 7).

**Treatment of Hypotension, Hypoperfusion, and Hypoxia**

Maintaining cerebral oxygen delivery after cardiac resuscitation is a mainstay of therapy. Oxygen delivery requires a sufficiently high cerebral perfusion pressure, a sufficiently low
cerebrovascular resistance (CVR), and adequate blood oxygen saturation.

Hypotension in the postarrest period can dangerously lower cerebral perfusion pressure. Although CBF is normally independent of perfusion pressure over a wide range of arterial blood pressure, such autoregulation is often lost in the injured brain. As a result, perfusion of ischemic tissue becomes passively dependent on arterial pressure, and hypotension can compromise CBF and result in significant additional brain damage. Therefore, after return of spontaneous circulation (ROSC), low arterial pressures should be rapidly normalized, using intravascular volume administration and vasopressors as needed. Because elevated arterial pressures may be needed to provide sufficient CBF, hypertension usually should not be treated in the postresuscitation period. Very high blood pressures may require treatment, but specific cutoffs are controversial. Generally, diastolic pressures may be allowed to run as high as 120 mm Hg without requiring treatment. In fact, hypertension is sometimes induced clinically or experimentally with vasopressors in an attempt to raise cerebral perfusion.
pressure and improve neurologic recovery. Because it is unproved, and because risks of this therapy include blood-brain barrier disruption and worsening of vasogenic edema, induced hypertension is not currently a standard therapy.

CVR after resuscitation from cardiac arrest is another determinant of CBF and may be affected by hyperventilation and microvascular patency. Although the cerebral circulation may lose its ability to adjust to blood pressure changes after ischemia, attenuated responsiveness to carbon dioxide and oxygen levels in arterial blood can still be present. Carbon dioxide is a potent vasoactive agent, and lowering of the arterial carbon dioxide partial pressure (Paco₂) by hyperventilation results in rapid reduction of CBF. Because reductions in CBF reduce total cerebral blood volume, hyperventilation may transiently abort brainstem herniation in the presence of critically elevated intracranial pressure (ICP) until osmotherapy or ventriculostomy can be initiated. When ICP is not elevated, however, the vasoconstriction and increased CVR caused by hyperventilation can cause potentially dangerous reductions in CBF. Although controversy surrounds whether increases in ICP are clinically significant after global ischemia, the measurement of ICP is generally not recommended in the management of adult cardiac arrest survivors. Generally, ventilation to maintain a Paco₂ between 35 and 40 mm Hg is safe and appropriate. CVR may also be elevated after cardiac arrest by endothelin-induced vasospasm or microvascular occlusion by leukocyte clumping or coagulation. Hemodilution, anticoagulation, and antplatelet agents have been studied in animals for effectiveness in mitigating microvascular occlusion with mostly negative results. Acute use of these agents to improve microcirculatory flow has not been studied in human cerebral ischemia.

Normal arterial oxygen saturation should be maintained after resuscitation from cardiac arrest. Because the injured brain may not be able to compensate for hypoxia by augmenting CBF, cerebral oxygen delivery may diminish rapidly as the oxygen content of blood decreases. Hyperoxia secondary to the use of 100% oxygen in the immediate postarrest period, however, has also been shown to increase oxidative brain injury in animal models of cardiac arrest and resuscitation. Normoxia or mild hyperoxia (Pao₂ of 80–120 mm Hg) should be maintained using the lowest fraction of inspired oxygen (FiO₂) possible. The use of 100% oxygen is appropriate during cardiac arrest, but FiO₂ should be titrated downward shortly after the ROSC. An important clinical trial to compare earlier use of normoxia after ROSC to the more typical prolonged period of postresuscitative hyperoxia has been proposed. Because hypoxia and hypercapnia must be avoided, controlled ventilation is appropriate in the period after resuscitation, with muscle relaxation and sedation if needed.

**Maintenance of Body Temperature**

Hyperthermia (or fever) exacerbates brain injury and worsens neurologic outcome. Elevated body temperature increases cerebral metabolic demand by 8 to 13% per degree Celsius, escalates glutamate release, increases oxygen free radical production, and increases cytoskeletal and blood-brain barrier breakdown with increased vasogenic edema. Core body temperature (usually rectal, bladder, or esophageal) should be accurately measured in patients resuscitated from cerebral ischemia. Hyperthermia may be treated with antipyretics, circulating air or water cooling systems, or evaporative cooling using water mist and fans. Aggressive treatment should, at a minimum, be used to prevent temperature increases in the postischemic period in all patients, and the practice of inducing therapeutic hypothermia is now emerging as a therapy for comatose survivors of cardiac arrest.

**Resuscitative Mild Hypothermia**

Hyperthermia was first reported more than 50 years ago to have a protective effect in global and focal brain ischemia and ranges from mild (32–34°C) to profound (5°C). The mechanism by which hypothermia conveys protection is uncertain, but several possibilities have been suggested. Hypothermia reduces glutamate release, metabolic demand, free radical formation, and production of inflammatory cytokines. Cell-signaling and genetic responses to cellular injury are also affected by hypothermia, and hypothermia may protect the brain from programmed neuronal cell death.

Mild hypothermia is easier to achieve and has fewer adverse effects than lower temperatures, and has consistently been found to be neuroprotective in experimental cerebral ischemia. Two multicenter prospective, randomized, controlled trials of mild hypothermia have now shown marked improvements in neurologic outcome in comatose survivors of out-of-hospital cardiac arrest. The improvements in neurologic outcome (recovery with minimal or no neurologic deficits at hospital discharge) and in mortality in patients treated with hypothermia in these trials are shown in Table 6-1. In these trials, the number needed to treat in order to have one additional patient with a good neurologic outcome was only about seven. The 2005 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care and the International Liaison Committee on Resuscitation recommend cooling unconscious adult patients after cardiac arrest to 33°C for 12 to 24 hours. Implementation of these guidelines has been slow and represents a failure of clinical translation. Barriers to adoption and the public health impact of widespread use have been reported.

**Table 6-1**

*Good neurologic outcome defined as recovery with no neurologic deficits or with moderate disability but living independently and working at least part time at 6 months.
†Good neurologic outcome defined as recovery with moderate, minimal, or no neurologic deficits at hospital discharge and discharge to home or acute rehabilitation facility.
Mild hypothermia can be induced through a variety of techniques. In both clinical trials of hypothermia after cardiac arrest, hypothermia was achieved by cooling the body surface with ice packs and cooling blankets. Surface cooling is noninvasive, and a variety of specialized devices have been developed to make it less labor intensive and faster, but some difficulties inherent with surface cooling are well described. These include slower than desired rates of cooling (0.3–0.6 °C/hr ± SD 0.3 °C/hr), overshooting and undershooting the temperature target (SD usually > 1 °C), and uncontrolled rewarming with very frequent rebound hyperthermia. Alternative core cooling methods have been investigated. A promising technique using infusions of ice cold intravenous fluids has been demonstrated and is more effective than would be expected based on the transfer of heat content alone. Although more invasive, endovascular cooling with a heat exchange catheter provides the most rapid cooling (1.4–6.3 °C/hr ± SD 0.3 °C/hr) and offers the tightest control of body temperature (SD usually < 0.3 °C) at the target temperature and during controlled rewarming. Designed to induce hypothermia or maintain normothermia in surgical patients, this new type of commercially available device is placed in the inferior vena cava through a femoral introducer and cools or warms the patient. In the two clinical trials, shivering was prevented with a nondepolarizing paralytic, and sedation was warmed passively to avoid hyperthermia and neuroprotection in experimental focal cerebral ischemia. Animal experimentation and the consensus recommendations suggest that cooling should be initiated as early and as rapidly as possible. Cooling may begin during the out-of-hospital phase of resuscitation, and may even be initiated prior to ROSC. In the positive clinical trials, hypothermia at 33 °C was achieved by 2 hours or 8 hours after ROSC and was maintained for either 12 hours or 24 hours. Patients were then allowed to rewarm passively or with a combination of passive and active rewarming. Rebound hyperthermia is common with passive rewarming and must be avoided. Although the clinical trials only enrolled patients resuscitated from cardiac arrest caused by ventricular fibrillation, there is clinical experience with resuscitative hypothermia in patients with cardiac arrest from other causes, and consensus recommendations support its use in such cases. Cooling of comatose survivors of out-of-hospital cardiac arrest requires a multidisciplinary hospital policy, and should be initiated as early as possible. In hospitals capable of hypothermic resuscitation, cooling is optimally started in the ED and maintained in the ICU. Regardless of cooling technique, patients cooled after cardiac arrest require pharmacologic therapy to prevent shivering because shivering effectively warms the patient. In the two clinical trials, shivering was prevented with a nondepolarizing paralytic, and sedation was maintained with midazolam with or without fentanyl. When paralysis is not clinically desirable, it may be possible to sufficiently lower the shivering threshold in awake patients with meperidine, buspirone, dexmedetomidine, or a combination of these. Shivering can sometimes also be reduced in a patient cooled by an endovascular catheter even when the core temperature is 33 °C by applying a warming blanket, since surface temperature receptors control thermoregulation to a much greater extent than core temperature receptors. Other pharmacologic treatments that may be used during induced hypothermia include antipyretics, which lower the core body temperature set point, even in normothermic patients, although to such a small degree that the effect is unlikely to be clinically relevant. More effective pharmacologic lowering of core body temperature is, however, being investigated. Neurtensin is an endogenous neuropeptide involved in thermoregulation that can induce hypothermia and neuroprotection in experimental models of cerebral ischemia.

Clinical trials of mild hypothermia in the resuscitation of patients with acute ischemic stroke, and two new clinical trials of mild hypothermia in adult and pediatric patients with traumatic brain injury are being performed and may expand the indications of this therapy in the future. Ongoing efforts to develop feasible methods of selective cooling of the brain after cardiac arrest, and studies of profound systemic hypothermia are still experimental.

**Treatment of Hyperglycemia**

Postischemic hyperglycemia has detrimental effects on CBF, metabolism, edema formation, and neurologic outcome. In experimental focal cerebral ischemia, profound hyperglycemia (>500 mg/dL) causes a more pronounced decrease in intracellular pH, increases brain lactate levels, and increases neuronal loss. Increased neuronal damage from hyperglycemia in global cerebral ischemia may also be glutamate-mediated. Observational studies in patients with stroke and survivors of cardiac arrest have shown that hyperglycemia after brain ischemia is strongly associated with worse outcomes in both diabetics and nondiabetics. In experimental studies, normoglycemia and mild insulin-induced hypoglycemia have been shown to improve neurologic function after focal and global ischemia. Interestingly, insulin itself may have a neuronal growth-factor-like effect that may theoretically also be neuroprotective. Thus, the best available evidence supports active treatment of hyperglycemia after global brain ischemia, and the administration of glucose should be avoided except in verified hypoglycemia.

**Seizure Management**

Seizures may result from global cerebral ischemia and may exacerbate the underlying brain injury. Seizure activity can increase brain metabolism by 300 to 400%, worsening the mismatch between oxygen delivery and demand in the post–arrest period, with greater metabolic failure and neuronal loss and worsened neurologic outcome. Although prevention of seizures has not been proved to improve neurologic recovery, seizures are clearly not desirable in the postischemic period. The prophylactic use of anticonvulsant drugs in patients resuscitated from cardiac arrest is controversial and is not standard care, but it is generally agreed that seizures should be quickly and effectively treated. Common therapeutic agents include benzodiazepines, phenytoin, and barbiturates. Each of these anticonvulsant drugs has also been considered as specific therapy for cerebral ischemia because of the antagonism of excitatory amino acids, sodium channel blockade, or effects on cerebral metabolism. Although these drugs are of proven value as anticonvulsants, other uses in cerebral ischemia are experimental and unproved.

**Immobilization, Sedation, and Head Position**

The comatose brain responds to external stimuli (e.g., physical examination, airway suctioning) with increases in cerebral
metabolism. This elevation of regional brain metabolism requires increased regional CBF at a time when the oxygen demand/perfusion ratios may be precariously balanced. Protection from afferent sensory stimuli with administration of titrated doses of sedative-anesthetic drugs and muscle relaxants may prevent oxygen supply/demand imbalance and improve the chances for neuronal recovery.

All activity that increases ICP (e.g., straining, coughing) should be restricted, and tracheal suction should be performed only when necessary and with care. There is no evidence to support the commonly recommended practice of elevating the head of the bed to reduce intracranial venous pressure, and this practice may even be harmful. Torsion or compression of neck veins should be avoided by eliminating compressive dressings and not rotating or flexing the head.

**CLINICAL OUTCOMES**

Global cerebral ischemia resulting from a period of cardiac arrest is a frequently fatal and highly morbid condition, but the prognosis for its victims is not universally poor. An increasing body of data is providing more complete and precise estimates of the functional outcomes and quality of life of survivors of cardiac arrest, and the results are better than many physicians assume.

The published experience in Olmsted County, Minnesota, between 1990 and 2000 may represent the best possible outcomes with currently available therapy. First-responders (including police and firefighters) with automated external defibrillators in that county responded to 330 patients with cardiac arrest, 200 (61%) of whom had ventricular fibrillation at presentation. The majority of patients with ventricular fibrillation (145 patients, 44% of all arrests) survived to hospital admission, and 84 patients (25%) were discharged alive. Remarkably, among these 84 survivors, 79 (24% of all arrests) left the hospital neurologically intact.

More typical outcomes were identified by a recent very large cohort study of outcomes in 8091 patients with cardiac arrest in Ontario, Canada. Survival was 5.2% at hospital discharge, and was 4.0% at 1 year. The vast majority of 1-year survivors (3% of all those with cardiac arrest), however, had no or minimal neurologic deficits, and the average quality of life indices of all survivors were as good as those for patients without a history of cardiac arrest. The Ontario experience echoes that of a Portuguese study, but other recent data on 6240 patients from studies in the Netherlands, Norway, and Switzerland all confirm a rate of survival to discharge home with minimal or no deficit of 8% in all out-of-hospital cardiac arrests. Quality of life among long-term survivors of cardiac arrest is consistently high in all of these studies, with low rates of patients in persistent vegetative states or requiring skilled nursing care. Overall, among those surviving to hospital admission, between 14 and 55% of patients will have good long-term neurologic outcomes.

Despite these data, nihilism is common among physicians treating patients with cardiac arrest and ischemic brain injury. This may be due, in part, to the fact that most survivors of cardiac arrest are comatose at the time of admission and are without early prognostic findings suggesting which patients will have a favorable outcome. Although predicting the outcome of coma is difficult, a recent meta-analysis suggests that the absence of pupillary and corneal reflexes at 24 hours and the absence of motor responses at 72 hours on physical examination are the best predictors of a poor neurologic outcome. Nihilism is of particular concern, however, and should be avoided because of the potential for poor prognoses to be self-fulfilling. In the near future, serum biomarkers of brain injury may identify the potential for neurologic recovery early in a patient’s course and help guide therapy. Until early predictions of outcome can be accurately made, the emergency physician should consider every survivor of cardiac arrest as having a significant chance of full recovery (14–55%), and should know that bad neurologic outcomes are usually fatal rather than chronically debilitating.

**SUMMARY**

Rapidly expanding knowledge about the pathophysiology of posts ischemic brain injury has stimulated the search for effective cerebral resuscitation therapies. Newly proven therapies like resuscitative hypothermia will continue to be developed and will improve the outcomes of patients with ischemic brain injury in future years. Although experimental work suggests many potentially promising brain resuscitation therapies, attention should also be paid to determining the benefits of existing “standard” therapies.

Because of the complexity and interconnectedness of the pathophysiologic cascades that occur after global cerebral ischemia, it is likely that a multifaceted therapeutic approach or “cocktail,” rather than a single pharmacologic agent, is needed to reduce neurologic damage after cardiac arrest.

It is crucial that the emergency physician recognize that the patient resuscitated from cardiac arrest is, contrary to outward appearance, in a dynamic stage of brain injury. At present, patients must be protected from further brain injury caused by hypotension, hypoperfusion, hypoxia, hyperthermia, hyperglycemia, or seizures. Comatose survivors of out-of-hospital cardiac arrest should now also undergo resuscitative hypothermia. In the future, cerebral resuscitation may also involve other specific pharmacologic interventions to derail the process by which brain cells slowly die after ischemic brain injury.

**KEY CONCEPTS**

- Neuronal injury is a dynamic process that continues for hours or days after an ischemic insult to the brain.
- Hypotension, hypoperfusion, and hypoxia must be avoided during brain resuscitation.
- Hyperthermia, hyperglycemia, and seizures should be treated promptly during brain resuscitation.
- Comatose survivors of out-of-hospital cardiac arrest should be rapidly cooled in the ED and maintained at 33°C in an ICU setting for 12 to 24 hours after resuscitation.

CHAPTER 7  Adult Resuscitation

Kevin R. Ward and Robert W. Neumar

PERSPECTIVE

Epidemiology

It is estimated that between 77,000 and 174,000 patients are treated for out-of-hospital cardiac arrest each year in the United States. The incidence of ventricular fibrillation as the initial rhythm has declined over time and is now estimated to be between 20 and 38%. Epidemiologic data from studies of out-of-hospital cardiac arrest show a wide range of outcomes. Return of spontaneous circulation (ROSC) that takes long enough to result in hospital admission ranges from 9 to 65%, whereas only 1 to 31% (median 6.4%) of patients survive to hospital discharge. Of patients surviving to hospital discharge, one third have persistent neurologic deficits, and less than half return to prearrest function. In patients meeting the inclusion criteria of clinical hypothermia trials, favorable outcome was reported in approximately 50% of cardiac arrest survivors who were admitted comatose and treated with hypothermia.

PRINCIPLES OF DISEASE

Etiology

Understanding the causes of cardiac arrest directs therapy and diagnostic testing during resuscitation and in the immediate postarrest period (Table 7-1). Cardiac arrest from a primary cardiac origin typically presents as ventricular fibrillation (VF) or less often as pulseless ventricular tachycardia (VT). Coronary artery disease is the most common pathologic condition found in patients who die suddenly from VF; autopsy studies show a 75% incidence of previous myocardial infarction (MI) and a 20 to 30% incidence of acute MI. Other anatomic abnormalities associated with sudden cardiac death caused by VF or VT include myocardial hypertrophy, cardiomyopathy, and specific structural abnormalities. Pulseless electrical activity (PEA) and asystole are less common initial presenting rhythms in patients with a cardiac cause of arrest. These rhythms most often occur as a deterioration of VF or VT or develop in response to resuscitation treatments, such as defibrillation.

Primary respiratory failure generally causes initial hypertension and tachycardia, followed by hypotension and bradycardia and progressing to PEA, VF, or asystole. Circulatory obstruction (e.g., tension pneumothorax, pericardial tamponade) and hypovolemia generally present with initial tachycardia and hypotension, progressing through bradycardia to PEA, but also may deteriorate to VF or asystole.

The most common metabolic cause of cardiac arrest is hyperkalemia, which is seen most frequently in patients with renal failure. Hyperkalemia results in progressive widening of the QRS complex, which can deteriorate to VT, VF, asystole, or PEA. Other electrolyte abnormalities (e.g., hypomagnesemia, hypermagnesemia, hypokalemia) may lead to significant dysrhythmias, but the frequency with which they cause cardiac arrest is not documented.

Cardiac arrest from drug toxicity has specific characteristics depending on the drug involved. Specific therapy directed at drug toxicity is essential but may not be immediately effective. Prolonged resuscitation efforts may be needed using a method that provides adequate perfusion.

Electrocution causes cardiac arrest through primary dysrhythmias or apnea. Alternating current in the range of 100 mA to 1 A generally causes VF, whereas currents greater than 10 A can cause ventricular asystole. Lightning produces a massive direct current electrocution that can result in asystole and prolonged apnea.

Hypothermia-induced cardiac arrest can present with any electrocardiogram (ECG) rhythm, and successful resuscitation depends on rapid rewarming, which often requires aggressive and invasive measures (e.g., peritoneal lavage, cardiopulmonary bypass [CPB], open-chest cardiac massage [OCCM]). Drowning is a form of asphyxia usually resulting in bradysystolic arrest. Because drowning often is accompanied by hypothermia, the victim may benefit from prolonged resuscitation efforts similar to resuscitation efforts for hypothermia.

CLINICAL FEATURES AND MANAGEMENT

Most cardiac arrest cases managed in the emergency department (ED) initially occur outside the hospital. An increasing number of first responders, nontraditional providers, and public venues are being equipped with automated defibrillators. Dramatic resuscitation rates have been achieved when these programs enable providers to deliver countershock within less than 4 to 5 minutes of arrest onset. Programs that fail to enable a significant number of patients to be defibrillated within this critical time window have limited or no effect on survival.

Advanced life support (ALS) units staffed by paramedics often have standing orders to follow advanced protocols. Because quality of cardiopulmonary resuscitation (CPR) and

**History and Physical Examination**

Historical information from the family, bystanders, and emergency medical services (EMS) personnel provides key information regarding cause and prognosis. Information surrounding the event includes whether the arrest was witnessed, the time of arrest, what the patient was doing (e.g., eating, exercising, trauma), the possibility of drug ingestion, time of initial CPR, initial ECG rhythm, and interventions by EMS providers. Important past medical history includes baseline health and mental status; previous heart, lung, renal, or malignant disease; hemorrhage; infection; and risk factors for coronary artery disease and pulmonary embolism. The patient’s current medications and allergies also should be obtained, if possible.

Physical examination of a cardiac arrest patient is necessarily focused on a few key goals: (1) ensure adequacy of airway maintenance and ventilation, (2) confirm the diagnosis of cardiac arrest, (3) find evidence of cause, and (4) monitor for complications of therapeutic interventions. This examination must occur in descending order of importance, simultaneous with therapeutic interventions, and must be repeated frequently to assess for response to therapy and occurrence of complications (Table 7-2).

Cardiopulmonary arrest is defined by the triad of unconsciousness, apnea, and pulselessness. The pulse must be palpated for in a large artery (carotid or femoral). If any question exists as to the diagnosis of pulselessness, CPR should be initiated and pulselessness confirmed by such methods as handheld vascular Doppler ultrasound or end-tidal carbon dioxide monitoring. Rapid bedside ultrasound may confirm loss of cardiac activity, but CPR should not be interrupted to determine this, except in the very late phases of the resuscitation, when termination of resuscitative efforts is contemplated. With sudden onset of circulatory arrest, as in VF, loss of consciousness occurs within 15 seconds, although agonal gasping respirations may persist for several minutes. A brief seizure may result from cessation of cerebral blood flow. Primary respiratory arrest results in transient tachycardia and hypertension that progress to loss of consciousness, bradycardia, and pulselessness, usually within 5 minutes.

After the initial minutes of cardiac arrest, physical examination may provide little evidence of the duration of arrest. Pupils dilate within 1 minute but constrict if CPR is initiated immediately and performed effectively. Dependent lividity and rigor mortis develop after hours of cardiac arrest. Temperature is an unreliable predictor of duration of cardiac arrest because it does not decrease significantly during the first hours of arrest. Moderate to severe hypothermia may cause cardiac arrest or may be caused by prolonged arrest, with opposite prognostic implications.

**Monitoring**

Traditional monitoring during CPR has relied on evaluation of the ECG in one or more leads and palpation of carotid or femoral artery pulses. Although the lack of a palpable pulse during CPR may indicate inadequate forward flow, the degree of forward flow cannot be estimated accurately in the presence of a palpable pulse because pressures generated during CPR may be transmitted equally to the venous and the arterial vasculatures. In addition, myocardial blood flow does not depend on the palpated arterial systolic pressure, but rather on the difference between aortic diastolic pressure and right atrial diastolic pressure (coronary perfusion pressure). ECG monitoring during cardiac arrest indicates the presence or absence of electrical but not mechanical activity. Although these two monitoring modalities may be the best attainable in
certain circumstances, they do not provide reliable information regarding the effectiveness of CPR and interventions or prognosis.

Unfortunately, no ideal monitoring technique provides all the information that might be desired during resuscitation, and even the modalities discussed next are often difficult or impossible to establish or interpret during CPR. A brief overview is provided of coronary perfusion pressure (CPP), end-tidal carbon dioxide (ET\textsubscript{CO}_2), and central venous oxygen saturation (Scv\textsubscript{O}_2) monitoring, which if available can be used to detect inadequate CPR with high specificity (Table 7-3). In addition, several of these techniques are useful in the immediate post-arrest period.

### Arterial Blood Pressure and Coronary Perfusion Pressure

Successful resuscitation of the arrested heart depends on generating adequate CPP during CPR, which has been directly correlated with myocardial blood flow.\textsuperscript{14} Animal and human studies indicate that a minimum CPP of 15 mm Hg is necessary to achieve ROSC if initial defibrillation attempts have failed.\textsuperscript{14,15} Unfortunately, CPP monitoring is rarely feasible in ED resuscitations of cardiac arrest patients, because it requires both an indwelling arterial pressure catheter and a central venous catheter, both transduced properly to provide simultaneous readings.

Invasive arterial blood pressure monitoring alone also may be helpful, but again, establishment of an indwelling arterial pressure catheter often is not feasible during cardiac arrest resuscitation in the ED. Studies have indicated that achievement of an arterial diastolic pressure of 40 mm Hg is highly predictive of ROSC and this relates to the CPP achieved at

such a diastolic pressure. Invasive, arterial pressure monitoring during CPR may also be useful to facilitate distinguishing electromechanical dissociation (EMD) from pseudo-EMD, provide immediate confirmation of ROSC, and assist in serial arterial blood gas monitoring. Although arterial and central venous catheters are most often placed in the postresuscitation phase of care, a significant number of patients initially achieving ROSC will reaerest in the ED, making these modalities helpful at this time in the patient’s subsequent resuscitation.

**End-tidal Carbon Dioxide**

Experimental and clinical studies have shown that ET\textsubscript{CO}_2 is a reliable indicator of cardiac output during CPR, but this depends on achieving several conditions during CPR in the out-of-hospital setting or in the ED. ET\textsubscript{CO}_2 depends on CO\textsubscript{2} production, alveolar ventilation, and pulmonary blood flow (i.e., cardiac output). If ventilation and CO\textsubscript{2} production are held constant, an increase or decrease in ET\textsubscript{CO}_2 reflects an increase or decrease in cardiac output, respectively. Although CO\textsubscript{2} production during cardiac arrest and CPR probably is not constant, small changes in CO\textsubscript{2} production and CPR probably is not likely to cause appreciable changes in ET\textsubscript{CO}_2 because of the extremely high mixed-venous CO\textsubscript{2} levels and large dead space created by cardiac arrest and CPR. Administration of sodium bicarbonate (NaHCO\textsubscript{3}) during CPR may cause a sudden large increase in mixed-venous CO\textsubscript{2}, however, which may produce a variable but transient increase in ET\textsubscript{CO}_2. Otherwise, with minute ventilation held constant (a desirable but often unmet goal,) only increased cardiac output during CPR and ROSC significantly increases ET\textsubscript{CO}_2.

In addition to correlations with cardiac output, animal and human studies show that ET\textsubscript{CO}_2 correlates with CPP and cerebral perfusion pressure during CPR. This correlation would be predicted based on the known relationship between mean arterial pressure and cardiac output when peripheral vascular resistance (PVR) is constant. With dramatic increases in PVR, however, as may occur with high-dose vasopressor therapy, cardiac output and ET\textsubscript{CO}_2 may decrease despite increased CPP.

ET\textsubscript{CO}_2 has the potential to guide adjustments in compression force and rate, maximize forward flow, and to detect CPR provider fatigue (Fig. 7-1).\textsuperscript{19} Resuscitation after cardiac arrest is likely to fail if ET\textsubscript{CO}_2 values are less than 10 mm Hg.\textsuperscript{20,21} In the absence of high-dose vasopressor therapy, ET\textsubscript{CO}_2 values less than 10 mm Hg should prompt the clinician to enhance the quality of CPR (either rate or force of compression) or consider more invasive maneuvers such as OCCM if the situation warrants and a good neurologic outcome is believed to be possible.

![Figure 7-1. Capnogram tracings of end-tidal carbon dioxide pressure (ET\textsubscript{CO}_2) during human cardiopulmonary resuscitation (CPR). 1, Effect of rescuer fatigue is shown at point A. Point B shows the effect of changing to a fresh rescuer. 2, Patient with pseudoelectromechanical dissociation. At point A, the patient is pulseless but has a persistent ET\textsubscript{CO}_2 value of 20 mm Hg without CPR; at point B, CPR is restarted; at point C, dopamine infusion is started; and at point D, CPR is stopped, and a pulse is palpated. 3, Sudden increase in ET\textsubscript{CO}_2 (point A) heralds the return of spontaneous circulation; pulses are palpated at point P. 4, Point A shows a transient increase in ET\textsubscript{CO}_2 such as occurs during bolus administration of sodium bicarbonate.](image-url)
ETCO₂ monitoring also can aid in the diagnosis and treatment of PEA. Patients in a state of pseudo-EMD (cardiac contraction that does not generate a pulse) may have pulsatile flow that simply cannot be detected by palpation of a pulse. In such circumstances, ETCO₂ levels may be elevated even without compressions. If, for example, the ETCO₂ is 10 mm Hg without compressions, consideration should be given to the possibility that the patient has spontaneous circulation but is profoundly hypotensive. In such cases, volume expansion or the use of vasopressors should be considered. ETCO₂ monitoring also is useful in rapidly detecting success of tension pneumothorax decompression, pericardiocentesis for pericardial tamponade, and fluid resuscitation for hypovolemia. ROSC causes immediate and significant increases in ETCO₂ before detection of a pulse by palpation. With the use of ETCO₂ monitoring, interruption of CPR is never necessary except to look for changes in the patient’s rhythm.

Finally, ETCO₂ monitoring is valuable in patients after cardiac arrest to detect sudden hemodynamic deterioration. Undetectable ETCO₂ during CPR indicates failure to intubate the trachea, massive pulmonary embolism, or inadequate chest compressions. Undetectable ETCO₂ even after prolonged cardiac arrest, cannot be attributed to cessation of CO₂ production.

Central Venous Oxygen Saturation

ScvO₂, when available, provides an additional method to monitor adequacy of resuscitative measures. The mixed-venous blood oxygen saturation in the pulmonary artery (SvO₂) represents the oxygen remaining in the blood after systemic extraction. Studies have shown a close correlation between ScvO₂ and SvO₂ during CPR. Because oxygen consumption remains relatively constant during CPR, as does arterial oxygen saturation (SaO₂) and hemoglobin, changes in ScvO₂ reflect changes in oxygen delivery by means of changes in cardiac output.

Although used primarily in the ICU setting, multilumen oximetric ScvO₂ catheters are placed in the same manner as regular central venous catheters and can be used to monitor ScvO₂ continuously in real time. ScvO₂ values normally range from 60 to 80%. During cardiac arrest and CPR, these values range from 25 to 35%, indicating the inadequacy of blood flow produced during CPR. Failure to achieve a ScvO₂ of 40% or greater has a negative predictive value for ROSC of almost 100%. ScvO₂ also helps to rapidly detect ROSC without interruption of chest compressions. ScvO₂ monitoring also is useful in the postarrest period to help titrate therapy and recognize any sudden deterioration in the patient’s clinical condition.

Echocardiography

The main usefulness of echocardiography is diagnostic, especially in patients with PEA. Echocardiography distinguishes EMD from pseudo-EMD. It also may be helpful in diagnosing mechanical causes of PEA, such as tension pneumothorax, pericardial tamponade, and pulmonary embolism. Echocardiography also is useful in guiding pericardiocentesis. In the postarrest period, echocardiography could prove to be valuable in determining the need for postarrest cardiac intervention or mechanical assistance of the failing heart.

Laboratory Testing

Intermittent arterial and venous blood sampling for gas or chemistry analysis is of limited utility during CPR. Typical blood gas findings during CPR are venous respiratory acidosis and arterial respiratory alkalosis. SaO₂ is usually greater than 94% during CPR and of little value in titrating resuscitation therapy except in the case of massive pulmonary embolism or unrecognized esophageal intubation. Although ScvO₂ indicates adequacy of CPR, a single measurement may not be as useful as continuous oximetric ScvO₂ monitoring.

Other laboratory studies during CPR serve more to confirm a diagnosis rather than guide therapy because results are usually available too late to make a difference. Serum electrolytes may be ordered to rule out hyperkalemia, hypokalemia, hypomagnesemia, hypercalcemia, and hypocalcemia; however, empiric therapy should be initiated immediately if a high clinical probability exists. Hemoglobin levels may indicate hemorrhage, but initial hemoglobin may be normal even in acute exsanguinating hemorrhage.

Resuscitation

Restoration of adequate cardiac function is the defining factor of ROSC, but restoration of normal brain function is the defining factor of successful resuscitation. The likelihood of achieving both of these goals decreases with every minute the patient remains in cardiac arrest. Although many interventions are specific to the presenting ECG rhythm, most therapeutic modalities and monitoring techniques are used in all rhythms, making separate algorithms redundant. In addition, a patient rarely remains in one ECG rhythm during the course of prolonged resuscitation.

Interventions must be performed rapidly and efficiently to maximize the chances of a good neurologic outcome. The quality of CPR is perhaps the most underappreciated component of the resuscitation effort. Important quality performance measures include compression rate (at least 100 per minute), compression depth (4–5 cm), duty cycle (50% of time in compression), full relaxation, and minimum pauses especially before and after defibrillation. Furthermore hyperventilation has been shown to be common and reduces cardiac output during CPR. A 30:2 compression-to-ventilation ratio is currently recommended for health care professionals in all adult resuscitation scenarios. Although recent evidence suggests chest-compression-only CPR is effective when performed by bystanders in the out-of-hospital setting, there is inadequate evidence to recommend this as an alternative strategy for health care professionals, except when inadequate personnel are present to provide compressions, ventilation, and other resuscitative activities. Intubation should be performed only when capable personnel are available and without interruption of chest compressions. Use of supraglottic airway adjuncts such as the esophageal tracheal Combitube and laryngeal mask airways may be good alternatives for airway management in the out-of-hospital phase of resuscitation with the main disadvantage being the inability to use the trachea as a route of drug administration. In addition to monitoring specific CPR performance parameters, physiologic monitoring, if available, can help optimize CPR quality for the individual patient (see Table 7-3). If the inadequacy of CPR is recognized early in the resuscitation despite optimized therapy, the physician in charge may consider more invasive measures such as OCCM if ROSC and a good neurologic outcome are possible. After prolonged arrest, however, clear indications that CPR is inadequate (based on appropriate monitoring techniques) should prompt cessation of resuscitation efforts.
**Figure 7-2.** Emergency treatment algorithm for treatment of cardiac arrest. If arrest is witnessed and known to be of short duration, immediate rhythm assessment and defibrillation or ventricular fibrillation/ventricular tachycardia (VF/VT) precede cardiopulmonary resuscitation (CPR). In cases of prolonged untreated VF/VT, 1 to 2 minutes of CPR before defibrillation may enhance the ability to achieve return of spontaneous circulation. EMD, electromechanical dissociation; PEA, pulseless electrical activity. Consider using biphasic defibrillation (120–150 J) vs. monophasic defibrillation (360 J). Generally ineffective unless initiated immediately after onset of asystole. Epinephrine, initial dose of 1 mg intravenous (IV) or intraosseous (IO) or 2.5 mg by endotracheal tube (ETT). Repeat every 3 to 5 minutes. Subsequent doses may be increased up to 0.1 mg/kg. An alternative to epinephrine is vasopressin, 40 U IV push. Vasopressin is potentially more effective if the presenting rhythm is asystole. The dose (40 U) can be repeated once in 3 minutes, followed by administration of epinephrine every 3 to 5 minutes. Amiodarone, 300 mg IV push followed by 150 mg every 30 minutes. Alternative antidyssrhythmic agents include lidocaine and bretylium. Magnesium sulfate, 1 to 2 g IV push in torsades de pointes or known hypomagnesemia. Atropine, 1 mg IV push or 2.5 mg by ETT. Repeat dose every 3 to 5 minutes to a total dose of 0.04 mg/kg. Open chest cardiac massage (OCCM) should be considered if (1) there are clear indications of inadequate blood flow during standard CPR, (2) duration of arrest is less than 20 minutes, and (3) the clinician judges that a potential exists for good neurologic outcome. AoDP, aortic diastolic pressure; CPP, coronary perfusion pressure; PEP, arterial and CVP lines to monitor CPP and/or ScvO₂ catheter. If CPR inadequate consider OCCM. The changes in end-tidal carbon dioxide partial pressure (ETCO₂) may not be predictive of myocardial blood flow after high-dose vasopressor therapy. Invasive monitoring should be performed only if adequate personnel are available and if it would not delay therapeutic interventions.
Ventricular Fibrillation and Pulseless Ventricular Tachycardia

VF and pulseless VT are treated identically because they are generally caused by the same mechanisms and respond to the same interventions. Traditional monophasic defibrillators using either a monophasic truncated exponential (MTE) or a monophasic dampened sinusoidal (MDS) waveform are rapidly being replaced by defibrillators that use biphasic waveforms. With biphasic defibrillation, the energy required for successful defibrillation, or the “defibrillation threshold,” is less than with monophasic defibrillation. This translates into an increased likelihood of initial defibrillation success and a decreased likelihood of postcountershock myocardial dysfunction. Despite documented advantages of lower defibrillation threshold and reduced myocardial injury using biphasic defibrillation, the data are currently inadequate to conclude that any specific waveform (biphasic or monophasic) is superior in achieving ROSC or survival to hospital discharge. New defibrillation technologies have stimulated reevaluation of optimal defibrillation strategies. Current consensus suggests that the most effective strategy is delivery of single countershocks at optimal energy levels with minimal pauses in CPR both before and immediately afterward.29 This is facilitated by placement of defibrillation paddles early in the resuscitation sequence, thus not requiring a pause while defibrillation paddles and gel pads are placed for each shock. Recommended countershock energies range from 150 to 200 J for biphasic truncated exponential (BTE) waveforms and 120 J for rectilinear biphasic waveforms.29 Health professionals should be familiar with the manufacturer-recommended countershock energies of the biphasic defibrillator(s) available in their practice setting. The recommended energy for single monophasic defibrillation is 360 J.29

A patient who develops VF or pulseless VT while on a cardiac monitor may remain conscious for 15 to 30 seconds. The patient should be encouraged to cough vigorously until a defibrillator is available. If the patient is unresponsive, chest compressions should be initiated immediately and continued until a defibrillator is available. Defibrillation without antecedent CPR is most likely to result in ROSC when administered in the early minutes of arrest. If the duration of untreated arrest is prolonged (>4–5 minutes), a brief period of chest compressions and ventilations (90–180 seconds) before defibrillation has been shown to improve the likelihood of ROSC and survival.30,31 The current consensus favors delivering a single countershock with minimal pause in chest compressions prior to defibrillation.32 Defibrillation is followed immediately by resumption of chest compressions for 2 minutes prior to rhythm check.32

VF and pulseless VT refractory to initial defibrillation should be treated with assisted ventilation and chest compression. Intravenous (IV) access and vasopressor therapy (epinephrine or vasopressin) should be administered and repeated every 3 to 5 minutes. Simultaneous administration of epinephrine and vasopressin does not improve outcome relative to epinephrine alone regardless of presenting rhythm.33

Defibrillation attempts should be preceded and followed by minimal interruptions of chest compression.32 Subsequent therapy for refractory VF and pulseless VT includes continued administration of vasopressors and antidyssrhythmic agents, followed by repeated countershocks. Antidyssrhythmics should be administered up to their maximum loading dose. The use of magnesium sulfate during VF and pulseless VT is of no proven efficacy except in torsades de pointes and possible hypomagnesemia. Specific indications for NaHCO₃ therapy include hyperkalemia and tricyclic antidepressant overdose. There is no evidence to support use of NaHCO₃ or other buffers as empiric treatment for metabolic acidosis during cardiac arrest. If a patient is defibrillated into a different pulseless rhythm, such as PEA or asystole, subsequent treatment should be modified to address those specific rhythms.

Pulseless Electrical Activity

PEA is defined as coordinated electrical activity of the heart (other than VT/VF) without a palpable pulse. This group of dysrhythmias includes EMD, in which no myocardial contractions occur, and pseudo-EMD, in which myocardial contractions occur but no pulse can be palpated. Although distinguishing EMD from pseudo-EMD may be useful in determining cause and guiding treatment, in most cases of primary PEA there is a natural progression from hypotension to pseudo-EMD to EMD.

True EMD is the result of a primary disorder of electromechanical coupling in myocardial cells. It often is associated with abnormal automaticity and conduction resulting in bradycardia and a wide QRS complex. Although the mechanism of uncoupling is unclear, it most often is associated with global myocardial energy depletion and acidosis resulting from ischemia or hypoxia. True EMD typically occurs after defibrillation following prolonged VF and is associated with hyperkalemia, hypothermia, and drug overdose.

Pseudo-EMD caused by global myocardial dysfunction is a transient state in the progression to EMD and has the same etiology. An additional cardiac cause of pseudo-EMD is papillary muscle and myocardial wall rupture, in which the ventricle continues to contract, but forward flow is greatly diminished. Pseudo-EMD also may be caused by primary supraventricular tachycardia. Additional extracardiac causes of pseudo-EMD include hypovolemia, tension pneumothorax, pericardial tamponade, and massive pulmonary embolism. Pseudo-EMD of extracardiac origin most often has narrow-complex tachycardia initially, which can progress to bradycardia with conduction abnormalities and QRS widening.

Treatment of PEA requires all general resuscitation measures, including CPR, intubation with assisted ventilation, IV access, and repeated administration of vasopressors. Initial assessment also should include vascular Doppler ultrasound, echocardiography, or ETCO₂ monitoring to distinguish EMD from pseudo-EMD. This is important since volume loading or continuous vasopressor infusion, which is not typically used in routine cardiac arrest resuscitation, may be helpful in cases of pseudo-EMD. PEA thought to result from supraventricular tachycardia should be immediately cardioverted. Atropine should be administered if the heart rate is less than 60 beats/min. These interventions alone are generally inadequate, unless the underlying cause of PEA is primary respiratory arrest or supraventricular tachycardia. Successful resuscitation of patients with PEA hinges on rapid diagnosis and treatment of the underlying cause. Physical examination may provide valuable clues to the underlying cause (Table 7-4). In hypoxia and hypovolemia, the diagnosis is based on response to empirical therapy, whereas other causes, such as pericardial tamponade, tension pneumothorax, and hypothermia, can be definitively diagnosed during resuscitation. Physical examination and monitoring are used to guide ongoing resuscitation efforts.

Asystole

Asystole represents complete cessation of myocardial electrical activity. Although asystole may occur early in cardiac arrest as a consequence of progressive bradycardia, asystole generally represents the end-stage rhythm after prolonged cardiac arrest caused by VF or PEA. Because the potential exists for an
organized rhythm or VF to appear as asystole in a single lead (if the rhythm vector is completely perpendicular to the lead vector), asystole always should be confirmed in at least two limb leads. It may be difficult to distinguish between extremely fine VF and asystole. Routine countershock of asystole to treat possible fine VF has not been shown to improve outcome, however.

Treatment of asystole requires all general resuscitation measures, including CPR, intubation with assisted ventilation, IV access, and repeated administration of vasopressors. In one randomized prospective out-of-hospital trial, improved survival to hospital admission and discharge was observed in patients presenting in asystole when two doses of vasopressin (40 IU) were given initially during resuscitation compared with standard-dose epinephrine (1 mg) followed by additional epinephrine if needed. Atropine should be administered with the first dose of vasopressor and repeated to a total dose of 0.04 mg/kg. Extensive research has shown that asystole in the out-of-hospital setting seldom responds to pacing. To be effective, pacing must be initiated within several minutes of arrest.

**Postarrest**

Resuscitation of a cardiac arrest victim does not end with ROSC. Management includes rapid diagnosis and treatment of the disorders that caused the arrest and the complications of prolonged global ischemia. Simultaneous management of these two entities makes caring for a postarrest patient particularly challenging.

Induction of prolonged therapeutic hypothermia in comatose survivors of cardiac arrest has been shown to improve survival and functional outcome in two prospective randomized clinical trials. Both studies enrolled only out-of-hospital patients with witnessed arrest and an initial rhythm of VF. The time to achieve target temperature (32–34°C) ranged from less than 2 hours to a median of 8 hours (interquartile range 4–16 hours), suggesting a broad therapeutic window. Hypothermia was maintained for 12 to 24 hours followed by gradual rewarming over 12 to 24 hours. Although these parameters provide guidelines within which postarrest hypothermia is effective, additional preclinical and clinical data are needed to determine the optimal temperature, time to achieve target temperature, and duration of therapy. In both studies, the rates of complications were not statistically different between groups. Although there are no absolute contraindications, relative contraindications include severe cardiogenic shock, life-threatening dysrhythmias, uncontrolled bleeding, preexisting coagulopathy, pregnancy, another obvious reason for coma (i.e., drug overdose or status epilepticus), known end-stage terminal illness, and a preexisting do-not-resuscitate status. Thrombolytic therapy does not preclude the use of hypothermia. Finally, although the current data are limited to patients with witnessed VF out-of-hospital cardiac arrest, induced postarrest hypothermia potentially should be effective in patients with other presenting rhythms and cardiac arrest presentations.

When the decision is made to treat the patient with therapeutic hypothermia, cooling efforts should be initiated as soon as possible. Practical methods of rapidly inducing hypothermia include ice packs (applied to the neck, inguinal areas, and axilla), fan cooling of dampened exposed skin, cooling blankets underneath and on top of the patient, and disabling of ventilator warming circuits. Rapid IV infusion of limited volumes (1–2 L) of 4°C saline facilitates rapid cooling, but additional measures are needed to maintain hypothermia. A number of automated surface cooling devices are now available that use chest and thigh pads and continuous temperature feedback from bladder or esophageal temperature probes. More invasive methods, including endovascular venous catheters, are also available and allow for rapid and precise control of temperature, but they require time and additional resources to institute. Shivering, which inhibits cooling, can be prevented with sedation and pharmacologic paralysis. However, prolonged paralysis should be avoided due to the risk of unrecognized seizure activity in postarrest patients. Target core body temperature should be 32 to 34°C and is best monitored by an indwelling temperature-sensitive bladder catheter or esophageal temperature probe.

When the patient is stabilized and cooling efforts are initiated, transfer to a critical care unit should occur as soon as possible. Although the optimal duration of postarrest hypothermia is unknown, target temperature should be actively maintained for 12 to 24 hours followed by gradual rewarming over 8 to 12 hours. Effective application of therapeutic hypothermia in comatose cardiac arrest survivors requires a coordi-
nated interdisciplinary effort and is best carried out using a predetermined goal-directed algorithm developed with input from emergency medicine, cardiology, and critical care physicians and nurses.

A simultaneous immediate concern in a comatose cardiac arrest survivor is whether the patient has an acute coronary syndrome. Diagnosing acute coronary syndrome in an unconscious patient after cardiac arrest presents a unique challenge. A standard 12-lead ECG should be obtained as soon as feasible after ROSC, with a right-sided 12-lead ECG, as indicated. In one study, 50% of patients achieving ROSC after out-of-hospital cardiac arrest were found to have acute coronary occlusion on cardiac catheterization, 10% of whom did not have ST segment elevation.13

Immediate percutaneous coronary intervention (PCI) is indicated in patients with ST-segment elevation myocardial infarction or new left bundle branch block (LBBB) and can be performed during therapeutic hypothermia.36-39 Given the potentially high incidence of occult critical coronary stenosis and myocardial ischemia, patients without ECG criteria for PCI represent a greater dilemma. Angioplasty of acute coronary lesions regardless of history or initial postarrest ECG has been shown to be an independent predictor of survival after CPR, such as with a phrenic central venous catheter. ScvO2 can be used as a reliable surrogate for SvO2, which eliminates the need for a pulmonary artery catheter.23 If ScvO2 is abnormally low (<65%), but hemoglobin and SaO2 values are normal, cardiac output is insufficient. Central venous pressure (CVP) should be used to deduce whether inadequate cardiac output is secondary to hypovolemia or impaired myocardial function. Augmenting CVP to levels between 10 and 15 mm Hg ensures adequate preload in most patients. If CVP is adequate and the patient has a mean arterial pressure of at least 70 mm Hg, therapy with an inotropic agent, such as dobutamine, should be initiated while considering reperfusion strategies. CVP measurements may decrease rapidly on initiation of dobutamine therapy. Additional volume expansion while maintaining a hemoglobin value of at least 10 g/dL should be provided as needed to maintain an adequate CVP.

The response to DO2-optimizing interventions can be monitored by continuous or serial ScvO2 measurements and serial lactate levels. An increase in ScvO2 coupled with a decrease in lactate levels indicates improved DO2. An unchanged ScvO2 level indicates the need to continue increase delivery. Persistently elevated lactate levels and low ScvO2 despite maximum pharmacologic support and volume management signal the need for additional interventions to optimize DO2 to prevent accumulation of oxygen debt, which will lead to death or the development of multisystem organ failure. Options to consider include revascularization or mechanical assistance in the form of intra-aortic balloon pulsation or extracorporeal support. The induction of mild hypothermia may assist in lowering the metabolic demands of tissues in the postarrest state. Figure 7-3 provides a goal-directed guide to care of the postarrest patient. Similar options should be considered in a patient with venous hyperoxia and elevated levels of lactate because the combination of these findings indicate severe microvascular dysfunction, which also leads to the accumulation of oxygen debt incompatible with survival. The incidence of this condition may increase with the increased use of potent vasopressors, such as vasopressin.

Systems should ensure prompt transfer of postarrest patients from the ED to the cardiac catheterization laboratory or an intensive care unit, where intensive monitoring can guide subsequent therapy to achieve the optimal patient outcome. Family members should be fully informed of the circumstances and the patient’s transfer. Unless prompt transfer to the ICU is anticipated and achieved, postarrest care should begin in the ED.
Therapeutic hypothermia is indicated in comatose survivors of witnessed cardiac arrest that had a presenting rhythm of ventricular fibrillation. It may also be effective in patients resuscitated from other cardiac arrest presentations. Relative contraindications include an unwitnessed cardiac arrest, severe cardiogenic shock, life-threatening dysrhythmias, uncontrolled bleeding, preexisting coagulopathy, pregnancy, another obvious reason for coma (i.e., drug overdose or status epilepticus), known end-stage terminal illness, and a preexisting do-not-resuscitate status. "Initiation of therapeutic hypothermia is not a contraindication to thrombolytic therapy. CPB, cardiopulmonary bypass; CVP, central venous pressure; DO2, oxygen delivery; ECG, electrocardiogram; HB, hemoglobin; IABP, intra-aortic balloon pulsation; MAP, mean arterial pressure; PCWP, pulmonary capillary wedge pressure; PTCA, percutaneous transluminal angioplasty; SAO2, mixed-venous oxygen saturation; VO2, oxygen consumption."
KEY CONCEPTS

- CPR quality, including minimizing chest compression pauses, is critical to successful resuscitation from cardiac arrest.
- Restoration of adequate cardiac function is the defining factor of ROSC. Restoration of normal brain function is the defining factor of successful resuscitation.
- Resuscitation of a cardiac arrest victim does not end with ROSC. Rapid diagnosis and proper management of the pathologic conditions that precipitated and resulted from the arrest as well as goal-directed hemodynamic management can improve outcome.
- Induced prolonged hypothermia (32–34°C for 12–24 hours) is the first and only post-ROSC intervention shown to improve survival and functional outcome of comatose cardiac arrest survivors.

CARDIAC ARREST

Perspective

Cardiac arrest is not rare in pediatric patients, occurring in 2 to 6% of children admitted to a pediatric intensive care unit (PICU)\(^1,2\) and about 16,000 children per year out-of-hospital in the United States (i.e., \(\approx 8-20/100,000\) children/year).\(^3,4\) These data suggest that the rate of in-hospital cardiac arrest is about 100-fold higher than that for out-of-hospital arrest.\(^5\)

Although outcomes from pediatric cardiac arrest were once considered dismal,\(^6,7\) more recent data indicate that pediatric cardiopulmonary resuscitation (CPR) is saving lives. As many as two thirds of in-hospital pediatric cardiac arrest patients can be initially resuscitated,\(^8-12\) and over 25% survive to hospital discharge. For out-of-hospital pediatric cardiac arrests, 30% attain return of spontaneous circulation, 24% survive to hospital admission, and 12% survive to discharge.\(^4\) In contrast to previous assertions in the literature, performing CPR in children is not an exercise in futility.\(^13\)

Etiologic and Pathophysiologic Categories of Cardiac Arrest

Cardiac arrests can result from many pathophysiologic processes. Three common pathways to arrest have been identified: asphyxial, ischemic, and arrhythmogenic. Asphyxial cardiac arrests are precipitated by acute hypoxia or hypercarbia and are the most common in children.\(^3,10,12\) Ischemic arrests are precipitated by inadequate myocardial blood flow, in children most commonly due to shock from hypovolemia, sepsis, or myocardial dysfunction. Finally, arrhythmogenic arrests are precipitated by ventricular fibrillation (VF) or ventricular tachycardia (VT). The immediate cause of arrest in two recent in-hospital studies was arrhythmogenic for 10%, asphyxial for 67%, and ischemic for 61% (many had both asphyxia and ischemia).\(^10,12\) The vast majority of out-of-hospital arrests are also either asphyxial or ischemic, and 5 to 20% are arrhythmogenic.\(^3,14\)

Distinguishing Principles of Disease

Children Are Different

Appropriate pediatric CPR differs from that for adults due to children’s differences in anatomy and physiology, as well as the differences in the pathogenesis of cardiac arrest and the common rhythm disturbances for children. In contrast to adults, children rarely suffer sudden VF cardiac arrest from coronary artery disease. The causes of pediatric arrests are more diverse and are usually secondary to profound hypoxia or asphyxia due to respiratory failure or circulatory shock. Prolonged hypoxia and acidosis impair cardiac function and ultimately lead to cardiac arrest. By the time the arrest occurs, all organs of the body have generally suffered significant hypoxic-ischemic insults.

The Four Phases of Cardiac Arrest

Cardiac arrest may be categorized into four “phases,” each with unique physiology and treatment strategies: (1) prearrest, (2) no flow (untreated cardiac arrest), (3) low flow (CPR), and (4) postresuscitation.

The Prearrest Phase. The prearrest phase is the period before the arrest. Because most out-of-hospital pediatric cardiac arrests are due to progressive asphyxia or ischemia, they can often be prevented by avoiding the precipitating insult. For example, infant and child car seats, and seat belts for older children, can prevent cardiac arrests resulting from motor vehicle collisions. Similarly, fences around swimming pools with self-closing gates can prevent drownings.

Both the BRESUS study in the United Kingdom and the AHA's National Registry of Cardiopulmonary Resuscitation
(NRCPR) data clearly demonstrate that most in-hospital cardiac arrests are asphyxial or ischemic rather than sudden arrhythmia-induced events.\textsuperscript{10,18,19} Most importantly, many of these arrests could be prevented by early recognition and treatment of respiratory failure and shock. This information has fueled interest in the development of medical emergency teams (aka rapid response teams) to recognize and treat respiratory failure and circulatory shock before progression to cardiac arrest.\textsuperscript{20,21} These issues were appreciated by the founders of the Pediatric Advanced Life Support (PALS) course, which was therefore designed to prevent cardiac arrests by early recognition and treatment of respiratory failure and shock in children.\textsuperscript{7} In the \textit{prearrest phase}, hospitalized children at high risk for a cardiac arrest should be in a monitored unit, where prompt diagnosis and treatment is available for respiratory failure, circulatory shock, and life-threatening arrhythmias.\textsuperscript{10}

The \textbf{No-Flow Phase (Untreated Cardiac Arrest)}. Interventions during the \textit{no-flow} phase of untreated pulseless cardiac arrest focus on early recognition of cardiac arrest and initiation of basic and advanced life support. Yet only a third of children with an out-of-hospital cardiac arrest are provided with bystander CPR.\textsuperscript{4,14} According to NRCPR data, 83\% of pediatric in-hospital arrests were witnessed, and the children were on monitors.\textsuperscript{10} It is becoming increasingly clear that any in-hospital pediatric cardiac arrest that does not occur in a monitored unit should be evaluated as a sentinel event or potentially an avoidable death.

The \textbf{Low-Flow Phase (Resuscitation)}. During untreated cardiac arrest, circulation has stopped (i.e., the \textit{no-flow} phase). Blood flow during CPR is generated by chest compressions. For children the main mechanism of blood flow is from cardiac compression. The cardiac output depends on the product of the stroke volume and heart rate. The force of compressions is a major determinant of stroke volume, and the rate of compressions is the sole determinant of heart rate. Stroke volume also depends on preload. Therefore, patients with cardiac arrests precipitated by circulatory shock (e.g., hypovolemic or septic shock) may need additional intravascular volume to generate an adequate stroke volume with chest compressions. Notably, excellent CPR can result in a cardiac output 10 to 25\% of that in normal sinus rhythm.

Adequate myocardial blood flow is necessary for return of spontaneous circulation. During CPR, myocardial blood flow depends on coronary perfusion pressure or the “driving pressure” of blood into the coronary arteries from the aorta (i.e., the difference between the aortic and right atrial pressures during the relaxation phase). If the coronary perfusion pressure falls below 15 mm Hg during CPR in adults, the likelihood for a return of spontaneous circulation is substantially decreased.\textsuperscript{22} Animal data suggest that outcomes improve as coronary perfusion pressure increases above 25 mm Hg.\textsuperscript{23} Moreover, even relatively brief interruptions to chest compressions (e.g., 4-second pauses for two rescue breaths) lead to substantial decreases in the aortic relaxation pressure and coronary perfusion pressure, thereby resulting in inadequate myocardial perfusion\textsuperscript{24,25} (Fig. 8-1).

\textbf{Circumferential Versus Focal Sternal Compressions}

In adults and animal models of cardiac arrest, circumferential CPR (e.g., vest CPR) provides better CPR hemodynamics than two-finger compressions. In smaller infants, the recommended CPR technique is to encircle the chest with both hands and depress the sternum with the thumbs, while compressing the thorax circumferentially (when the resuscitator’s hands are relatively large enough to do so; Fig. 8-2).\textsuperscript{14} This “two-thumb” circumferential compression technique results in higher systolic and diastolic blood pressures and a higher pulse pressure than traditional two-finger compression of the sternum.\textsuperscript{26,27}

\textbf{Chest Compression Rate}

Another important determinant of myocardial blood flow is the chest compression rate. Although the optimal chest compres-
Critical Management Principles

Lower rate. In addition, vasoconstrictors, such as epinephrine or vasopressin, preferentially direct the cardiac output away from the skin and toward the myocardium. This phenomenon, occurring in 23% of chest compressions, can be balanced against the adverse consequence of impeding venous return to the heart.

The present recommendations for CC:V ratios during CPR are based on rational conjecture from animal, manikin, and mathematical models, as well as educational theory on the retention of skills in adult learners. In the 2005 AHA Guidelines, a universal CC:V ratio of 30:2 is recommended for single-person bystander CPR. For two-rescuer CPR, a 15:2 ratio is recommended for all children beyond the newly born period. For the newly born, a ratio of 3:1 is recommended, resulting in a greater number of ventilations per minute, but nearly the same number of compressions (100/min vs. 90/min). This recommended ratio was arrived at by consensus to balance educational issues (i.e., the benefit to single-rescuer bystanders of remembering only one compression to ventilation ratio of 30:2) with what is known about the physiology of the cardiac and pulmonary circulations of children during cardiac arrest.

Leaning

Along with the increased recognition that chest compressions are often too slow and too shallow (i.e., not forceful enough), investigators have focused on the problem of leaning during CPR. Leaning, or incomplete decompression of the chest during the relaxation phase of chest compressions, is a well-recognized phenomenon. In a manikin study of CPR-trained lay volunteers, Aufderheide observed incomplete chest wall decompression in 6 of 13 resuscitations. In a larger observational study of out-of-hospital cardiac arrests, incomplete release in greater than 10% of compressions was observed in 16 of 173 (9%) CPR episodes. Observations during in-hospital pediatric CPR indicate that “leaning” is a common phenomenon, occurring in 23% of chest compressions.
“Leaning” pressures of approximately 15% of body weight may affect intrathoracic pressure and theoretically affect the hemodynamics of CPR.\(^{54-48}\)

### Real-Time Cardiopulmonary Resuscitation Feedback

In an effort to optimize CPR quality, new technology has been developed that monitors CPR through a force sensor and accelerometer on the chest. This information is transmitted to a defibrillator monitor to provide quantitative verbal feedback to the rescuer on the rate and force of compressions as well as the frequency and volume of ventilations. Recent studies document that poor-quality CPR, as analyzed by a feedback device, reduces the likelihood of defibrillation success,\(^{35}\) and rescuers can use this type of automated feedback to improve CPR quality and compliance with current guidelines.\(^{49}\) A recent pilot study suggests that real-time corrective feedback during pediatric CPR can improve CPR performance, but more information on the accuracy and appropriateness of CPR performance targets is warranted.\(^{50}\) The optimal goals for aortic pressures during pediatric CPR are unknown. Animal data and adult data suggest that a reasonable goal for the aortic diastolic (or relaxation) pressure is greater than 20 to 30 mm Hg.\(^{22,23}\) Similarly, a reasonable goal for the aortic systolic (or compression) pressure is greater than 50 mm Hg for a newborn, 60 mm Hg for an infant, 70 to 80 mm Hg for a child, and 80 to 90 mm Hg for an adolescent.

### “Hands Only” Bystander Cardiopulmonary Resuscitation

There has been increasing interest in chest compressions alone, or “hands-only” CPR for sudden cardiac arrest. The AHA recently issued a science advisory statement recommending hands-only CPR for adult sudden cardiac arrest.\(^{51}\) This recommendation specifically excludes pediatric cardiac arrests and arrests secondary to progressive respiratory failure and hypoxia (i.e., asphyxial arrests). Hands-only bystander CPR is the treatment of choice for a bystander without formal CPR training and a CPR-trained bystander who “is not confident in his or her ability to provide rescue breaths with minimal interruptions to chest compressions.” For a CPR-trained bystander who “is confident in his or her ability to provide rescue breaths with minimal interruptions to chest compressions, the bystander should provide either conventional CPR using a 30:2 compression-to-ventilation ratio or hands-only CPR.” Finally, because mouth-to-mouth rescue breathing is a complex psychomotor task that is difficult to teach by telephone, the simpler technique of hands-only CPR is the recommended technique for telephone-directed CPR.

Many animal studies have established that continuous chest compressions without rescue breathing is as effective as chest compressions with rescue breathing for the first several minutes of CPR for VF.\(^{35,52-55}\) Since oxygenation and ventilation are clearly important for survival from any cardiac arrest, why is rescue breathing not initially necessary for VF? Immediately after an acute fibrillatory cardiac arrest, aortic oxygen and carbon dioxide concentrations do not vary from the prearrest state because there is no blood flow and aortic oxygen consumption is minimal. Therefore, when chest compressions are initiated, the blood flowing from the aorta to the coronary and cerebral circulations provides adequate oxygenation at an acceptable pH. At that time, myocardial and cerebral oxygen delivery is limited more by blood flow than oxygen content. Adequate oxygenation and ventilation can continue without rescue breathing because the lungs serve as a relatively high oxygen/low carbon dioxide reservoir during the low-flow state of CPR. In addition, ventilation can occur due to chest compression-induced gas exchange and spontaneous gasping during CPR in victims of sudden cardiac arrest. Therefore, arterial oxygenation and pH can be adequate with chest compressions alone in VF arrests.\(^{52,53,56}\)

Six clinical out-of-hospital studies in adults found that outcomes were as good or better after hands-only bystander CPR as with standard bystander CPR.\(^{57-63}\) One of these studies was a randomized, controlled prospective study of telephone-directed CPR, whereas the other five were observational studies of outcomes after bystander CPR.\(^{57-63}\)

### Asphyxia and Pediatric Cardiac Arrest

Chest compression (i.e., hands-only) CPR for children is not recommended. Foregoing ventilation in the pediatric patient is not prudent because respiratory arrest and asphyxia generally precede pediatric cardiac arrest. During asphyxia, blood continues to flow to tissues; therefore, arterial and venous oxygen saturations decrease while carbon dioxide and lactate continue to increase for many minutes before progression to cardiac arrest. In addition, continued pulmonary blood flow before the cardiac arrest depletes the pulmonary oxygen reservoir. In this circumstance, rescue breathing can be life-saving.

Not surprisingly, animal studies of bystander CPR for asphyxia-precipitated cardiac arrests demonstrate that the addition of rescue breathing to compressions results in much better outcomes than chest compressions alone.\(^{54,65}\) Chest compressions alone, however, were superior to no CPR at all, even with hypoxia-induced cardiac arrest. These studies support the need for rescue breathing as a critical component of CPR for pediatric asphyxia-precipitated cardiac arrests. However, approximately 10% of both in-hospital and out-of-hospital pediatric cardiac arrests are arrhythmogenic arrests precipitated by VF or VT. For an older child with a sudden collapse from cardiac arrest (i.e., presumed VF or VT), hands-only CPR is a reasonable choice for bystander CPR.

### Advanced Life Support Medications During the Low-Flow Phase of Cardiopulmonary Resuscitation

Figure 8-3 demonstrates a simplified algorithm for pediatric pulseless cardiac arrest. In addition, Table 8-1 lists medicines commonly used during CPR. Table 8-1 also includes the dosage and appropriate indications for these medications.

Although animal studies indicate that epinephrine can improve initial resuscitation success after both asphyxial and VF cardiac arrests, no single medication has been shown to improve survival to hospital discharge outcome from pediatric cardiac arrests. Medications commonly used for CPR in children are vasopressors (epinephrine or vasopressin), calcium chloride, sodium bicarbonate, and antiarrhythmics (amiodarone or lidocaine). During CPR, epinephrine’s alpha-adrenergic effect increases systemic vascular resistance, increasing diastolic blood pressure, which in turn increases coronary perfusion pressure and blood flow and increases the likelihood of the return of spontaneous circulation (ROSC). Epinephrine also increases cerebral blood flow during CPR because peripheral vasoconstriction directs a greater proportion of flow to the cerebral circulation. The beta-adrenergic effect increases myocardial contractility and heart rate and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi, although this effect is of less importance. Epinephrine also changes the character of VF (i.e., higher amplitude, more “coarse”), increasing the likelihood of successful defibrillation.

Continuous nebulizer: 0.5 mg/kg/hr INH (max 20 mg/hr)                                                                                                        |
| Alprostadil (PGE1)       | Ductal-dependent congenital heart disease (all forms)  
0.05–0.1 µg/kg/min IV/IO infusion initially, then 0.01–0.05 µg/kg/min IV/IO                                                                                                                                  |
| Amiodarone               | SVT, VT (with pulses)  
5 mg/kg IV/IO *load* over 20–60 min (max 300 mg), repeat to daily max 15 mg/kg (or 2.2 g) Pulseless arrest (ie, VF/pulseless VT)  
5 mg/kg IV/IO *bolus* (max 300 mg), repeat to daily max 15 mg/kg (or 2.2 g)                                                                                       |
| Atropine sulfate         | Bradycardia (symptomatic)  
0.02 mg/kg IV/IO (min dose 0.1 mg, max single dose child 0.5 mg, max single dose adolescent 1 mg), may repeat dose once, max total dose child 1 mg, max total dose adolescent 2 mg  
0.04–0.06 mg/kg ETT  
Toxins/overdose (eg, organophosphate, carbamate)  
0.02–0.05 mg/kg (<12 years) *OR* 0.05 mg/kg (>12 years) IV/IO initially, repeat q 20–30 min until atropine effect (dry mouth, tachycardia, mydriasis) is observed or symptoms reverse |
| Calcium chloride 10%     | Hypocalcemia, hyperkalemia, hypermagnesemia, calcium channel blocker overdose  
20 mg/kg (0.2 mL/kg) IV/IO *slow* push during arrest or if severe hypotension, repeat PRN                                                                                                             |
| Dexamethasone            | Croup  
0.6 mg/kg PO/IM/IV (max 16 mg)                                                                                                                                                                           |
| Dextrose (Glucose)       | Hypoglycemia  
0.5–1 g/kg IV/IO (D\(_5\)W 2–4 mL/kg; D\(_\text{o}\)W 5–10 mL/kg)                                                                                                                                                     |
| Diphenhydramine         | Anaphylactic shock  
1–2 mg/kg IV/IO/IM q 4–6 hr (max 50 mg)                                                                                                                                                                           |
| Dobutamine               | Congestive heart failure, cardiogenic shock  
2–20 µg/kg/min IV/IO infusion; titrate to desired effect                                                                                                                                                           |
| Dopamine                | Cardiogenic shock, distributive shock  
2–20 µg/kg/min IV/IO infusion; titrate to desired effect                                                                                                                                                           |
| Epinephrine             | Pulseless arrest, bradycardia (symptomatic)  
0.01 mg/kg (0.1 mL/kg) 1:10,000 IV/IO q 3–5 min (max 1 mg: 1 mL)  
0.1 mg/kg (0.1 mL/kg) 1:1000 ETT q 3–5 min  
Hypotensive shock  
0.1–1 µg/kg/min IV/IO infusion (consider higher doses if needed) Anaphylaxis  
0.01 mg/kg (0.01 mL/kg) 1:1000 IM in thigh q 15 min PRN (max 0.5 mg) *OR*  
Auto-injector 0.3 mg (wt ≥ 30 kg) IM or Child Jr auto-injector 0.15 mg (wt 10–30 kg) IM  
0.01 mg/kg (0.1 mL/kg) 1:10,000 IV/IO q 3–5 min (max 1 mg) if hypotension  
0.1–1 µg/kg/min IV/IO infusion if hypotension despite fluids and IM injection  
Asthma  
0.01 mg/kg (0.01 mL/kg) 1:1000 SQ q 15 min (max 0.5 mg; 0.5 mL)  
Croup  
0.25–0.5 mL *racemic* solution (2.25%) mixed in 3 mL NS INH *OR* 3 mL 1:1000 INH  
Toxins/Overdose (eg, beta-adrenergic blocker, calcium channel blocker)  
0.01 mg/kg (0.1 mL/kg) 1:10,000 IV/IO (max 1 mg); if no response, consider higher doses up to 0.1 mg/kg (0.1 mL/kg) 1:1000 IV/IO  
0.1–1 µg/kg/min IV/IO infusion (consider higher doses)  
Furosemide               | Pulmonary edema, fluid overload  
1 mg/kg IV/IM (usual max 20 mg if not chronically on loop diuretic)                                                                                                                                              |
| Hydrocortisone          | Adrenal insufficiency  
2 mg/kg IV bolus (max 100 mg)                                                                                                                                                                                  |
| Inamrinone              | Myocardial dysfunction and increased SVR/PVR  
Loading dose: 0.75–1 mg/kg IV/IO slow bolus over 5 min (may repeat twice to max 3 mg/kg), then 5–10 µg/kg/min IV/IO infusion                                                                                      |
| Ipratropium bromide     | Asthma  
250–500 µg INH q 20 min PRN × 3 doses                                                                                                                                                                          |
Prospective and retrospective studies indicate that use of high-dose epinephrine in adults or children (0.05–0.2 mg/kg) does not improve survival and may be associated with a worse neurologic outcome.66–69 A randomized, blinded, controlled trial of rescue high-dose epinephrine versus standard-dose epinephrine following failed initial standard-dose epinephrine for pediatric in-hospital cardiac arrest demonstrated a worse 24-hour survival rate in the high-dose epinephrine group (1/27 vs. 6/23, \( P < 0.05 \)).70 High-dose epinephrine cannot be recommended for routine use during CPR.

**The Postresuscitation Phase.** The postarrest syndrome is a unique and complex combination of pathophysiologic processes that occurs after successful resuscitation. This postarrest syndrome includes (1) postarrest brain injury, (2) postarrest myocardial dysfunction, (3) systemic ischemia-reperfusion response, and (4) the unresolved pathologic process that caused the cardiac arrest.

Clinical manifestations of postarrest brain injury include coma, seizures, myoclonus, varying degrees of neurocognitive dysfunction (ranging from memory deficits to persistent vegetative state), and brain death. Mild induced hyperthermia is the most well-established postresuscitation therapy for adult postarrest brain injury. Two seminal articles established that induced hyperthermia (32–34°C) could improve outcome for comatose adults after resuscitation from VF cardiac arrest.71,72 In both randomized controlled trials, the inclusion criteria were patients older than 18 years who were persistently comatose after successful resuscitation from nontraumatic VF. Interpretation and extrapolation of these studies to children are difficult. Fever following cardiac arrest, brain trauma, stroke, and other ischemic conditions is associated with poor neurologic outcome. Hyperthermia following cardiac arrest is common in children.73 It is reasonable to believe that mild induced systemic hyperthermia may benefit children resusc-
tated from nontraumatic cardiac arrest. However, benefit from this treatment has not been rigorously studied and reported in children or in any patients with non-VF arrests. Multicenter trials of induced hypothermia after both in-hospital cardiac arrest and traumatic arrest are ongoing. Emerging neonatal trials of selective brain cooling and systemic cooling show promise for this therapy in neonatal hypoxic-ischemic encephalopathy, suggesting that induced hypothermia may improve outcomes.74

Postarrest myocardial dysfunction and hypotensive shock are very common among human survivors of cardiac arrest. For example, Laurent and colleagues reported that 90 of 165 consecutive patients admitted to the ICU after successful resuscitation following an out-of-hospital cardiac arrest needed vasoactive infusions for hypotensive shock.75 Other studies have similarly demonstrated that left ventricular dysfunction and hypotension are common among adult and pediatric survivors following cardiac arrest and are generally reversible among long-term survivors.81,72,76-80 Interestingly, postarrest myocardial dysfunction appears to be pathophysiologically similar to sepsis-related myocardial dysfunction, including increases in inflammatory mediator and nitric oxide production.75,77,78,81,82 Although the optimal management of postarrest hypotension and myocardial dysfunction have not been defined, data suggest that aggressive hemodynamic support may improve outcomes. Controlled trials in animal models have shown that dobutamine, milrinone, or levosimendan can effectively ameliorate postarrest myocardial dysfunction.83-87 In clinical observational studies, fluid resuscitation has been provided for patients with hypotension and concomitant low central venous pressure, and various vasoactive infusions, including epinephrine, dobutamine, and dopamine, have been provided for the myocardial dysfunction.71,72,76-80

How should patients be treated in the postarrest setting? An organized multidisciplinary postresuscitation protocol begins before the patient arrives at the hospital, continues in the emergency department (ED), and is tailored in the intensive care unit (ICU). Such a protocol that includes hemodynamic support, induced hypothermia, and percutaneous coronary intervention where indicated appears to improve outcomes in adults.80 Postarrest myocardial dysfunction and hemodynamic instability are common and should be anticipated. Therefore, continuous electrocardiographic and hemodynamic monitoring should be provided for all patients following successful resuscitation from a cardiac arrest. Furthermore, postarrest echocardiography should be considered for monitoring myocardial function. Reasonable interventions for vasodilatory shock with low central venous pressure include fluid resuscitation and vasoactive infusions. Appropriate considerations for left ventricular myocardial dysfunction include inotropic infusions and afterload reduction.

Pediatric Ventricular Fibrillation and Ventricular Tachycardia

Although asystole and pulseless electrical activity (PEA) are the most common rhythms seen in in-hospital pediatric cardiac arrest, VF or pulseless VT are not rare.88 VF/VT may occur as the primary inciting arrest rhythm (i.e., arrhythmogenic arrest) due to a variety of underlying myocardial pathologies (acute infectious cardiomyopathies, congenital heart disease, Wolff-Parkinson-White syndrome, etc.) or electrolyte derangements. Of 1005 pediatric in-hospital cardiac arrests in the NRCPR database, 27% had VF/VT at some point during the resuscitation, 10% as an initial rhythm, an additional 15% as subsequent VF/VT (i.e., some time later during the resuscitation effort), and the timing could not be determined for 2%.12 Among pediatric cardiac ICU patients, as many as 41% of the arrests have been associated with VF/VT.88 Asphyxia-associated VF (presumably subsequent VF) is also well documented in pediatric drowning patients.89

Traditionally, VF and VT have been considered “good” cardiac arrest rhythms, resulting in much better outcomes than after asystole and PEA. However, NRCPR data establish that survival to discharge was more common among children with initial VF/VT than among children with subsequent VF/VT (35% vs. 11%; odds ratio 2.6, 95% confidence interval 1.2–5.8).12 Surprisingly, the subsequent VF/VT group had worse outcomes than children with asystole/PEA (11% vs. 27% survival). These data suggest that outcomes after initial VF/VT in children (an arrhythmic arrest) are “good,” but outcomes after subsequent VF/VT (i.e., VF/VT in the setting of an asphyxial or ischemic arrest) are worse, even compared with initial asystole/PEA without subsequent VF/VT.

Defibrillation

Defibrillation, defined as termination of VF, is necessary for successful resuscitation from VF cardiac arrest. The goal of defibrillation is return of an organized electrical rhythm with a palpable pulse. When prompt defibrillation is provided soon after the induction of VF in a cardiac catheterization laboratory, the rates of successful defibrillation and survival approach 100%. When automated external defibrillators are used within 3 minutes of adult-witnessed VF, long-term survival can occur in more than 70% of cases.90,91 In general, the mortality rate increases by 5 to 10% per minute of delay to defibrillation.92 Provision of high-quality CPR can improve outcomes and save lives. Because pediatric cardiac arrests are commonly due to progressive asphyxia or shock (or both), the initial treatment of choice is prompt CPR, not defibrillation. Therefore, rhythm recognition has been deemphasized in the latest PALS guidelines compared with adult cardiac arrests.14 This historical emphasis must be balanced against the increasing evidence that VF in children is not rare, outcomes from arrhythmic VF arrests are superior to those from other types of cardiac arrests, and that early rhythm diagnosis is necessary for optimal care.

Because of the increasing awareness that “shockable” rhythms are not uncommon in children, greater attention has been focused on the dose for pediatric defibrillation. The recommended shock dose is 2 to 4 J/kg, which is based on animal studies of short-duration VF and a single retrospective study of in-hospital (short duration) VF with 91% (52/57) defibrillation success.93 More recent piglet and out-of-hospital pediatric data indicate that 2 J/kg is often ineffective at terminating fibrillation.94,95 In-hospital pediatric defibrillation data also suggest that 2 J/kg is often ineffective at terminating fibrillation.96 Animal and clinical data suggest that a single pediatric dose of 50 J (i.e., the dose in pediatric AEDs) can be quite effective at terminating fibrillation.

SPECIAL CONSIDERATIONS: APPARENT LIFE-THREATENING EVENT, SUDDEN INFANT DEATH SYNDROME, AND DISCONTINUATION OF CARDIOPULMONARY RESUSCITATION

Sudden Infant Death Syndrome

Perspective

Passed in 1974, the Sudden Infant Death Syndrome (SIDS) Act assigned the responsibility for SIDS research to the National Institute of Child Health and Human Development (NICHD)
and provided focus for public information.\textsuperscript{97,98} The NICHD established the first nationally recognized definition of SIDS as well as other terms describing infants who present with apnea, periodic breathing, and cardiopulmonary distress.\textsuperscript{99}

\textbf{Apnea} is a cessation of airflow. The respiratory pause may be central or diaphragmatic (i.e., no respiratory effort), obstructive (usually caused by upper airway obstruction), or mixed. Short (<15 sec) periods of central apnea can be normal at all ages.

\textbf{Pathologic Apnea} is an abnormal respiratory pause that is prolonged (>20 sec), or is associated with cyanosis, marked pallor, hypotonia, or bradycardia.

\textbf{Apnea of Prematurity (AOP)} is periodic breathing with pathologic apnea in a premature infant. AOP usually ceases by 37 weeks’ gestation (menstrual dating) but occasionally persists past term.

\textbf{Apnea of Infancy (AOI)} is an unexplained episode of cessation of breathing for 20 seconds or longer or a shorter respiratory pause associated with bradycardia, cyanosis, pallor, or marked hypotonia. This generally refers to infants who are older than 37 weeks’ gestational age at the onset of pathologic apnea.

\textbf{Periodic Breathing (PB)} is a breathing pattern in which three or more respiratory pauses occur of greater than 3 seconds’ duration with less than 20 seconds of respiration between the pause. Periodic breathing may be a normal event.

\textbf{Breath-holding Spells} occur when infants perform a Valsalva maneuver in response to pain, fright, crying, coughing, or defecation. During the spell, minute ventilation decreases without any adverse effects. Breath-holding spells, however, if severe and prolonged, may result in cyanosis, unconsciousness, and seizures.

\textbf{Apparent Life-threatening Event (ALTE)} is an episode that is frightening to the observer and is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking, or gagging. Often the observer fears that the infant has died. Terms for apparent life-threatening events, such as near-miss SIDS or aborted crib death are no longer used because they imply an unproven, misleading association between an ALTE and SIDS.

\textbf{Sudden Infant Death Syndrome (SIDS)} is “the sudden death of an infant under one year of age, which remains unexplained after a thorough case investigation, including performance of a complete autopsy, examination of the death scene, and review of the clinical history.”

The National Center for Health Statistics reports that SIDS is the third leading cause of death in infants, accounting for 8% of deaths in children younger than 1 year of age.\textsuperscript{100} SIDS may occur at any time during the first 2 years of life, but it is rare (1%) in children younger than 1 month of age and in those older than 1 year of age (2%). Ninety-five percent of SIDS infants die before 6 to 8 months, with a peak occurring between 2 and 4 months of age.\textsuperscript{101-104} Some epidemiologic variation occurs among different racial and ethnic groups, with black, Native American, and Alaskan Native infants having rates two to three times higher than the national average.\textsuperscript{105-107} Other epidemiologic risk factors include male sex and multiple births.\textsuperscript{99,108}

\textbf{Distinguishing Principles of Disease}

\textbf{Risk Factors for Sudden Infant Death Syndrome}. Although a number of risk factors have been studied; the following factors have been consistently associated with an increased risk of SIDS: maternal smoking during pregnancy, preterm or low birth weight, male gender, prone sleep position, and overheating.\textsuperscript{105,108-112}

Approximately 20% of all SIDS cases occur in the preterm population. Compared with age-matched controls, infants born at less than 37 weeks and less than 33 weeks’ gestation are 5 and 16 times, respectively, more likely to die of SIDS.\textsuperscript{112}

The most important modifiable risk factor for SIDS is prone sleeping. In 1992, the American Academy of Pediatrics (AAP) recommended that infants be placed to sleep in a nonprone position to reduce the risk of SIDS.\textsuperscript{113} The “Back to Sleep” (BTS) campaign was initiated in 1994 under the leadership of the NICHD, as a collaborative effort of the U.S. Public Health Service, the AAP, the SIDS Alliance, and the Association of SIDS and Infant Mortality Programs. Since then, the frequency of prone sleeping has decreased 50 to 90% worldwide as has the rate of SIDS.\textsuperscript{105,108,109,114-119}

The prevalence of prone sleeping in the United States decreased from 70% in 1992 to 13% in 2004.\textsuperscript{105,120} Racial disparities in rates of SIDS deaths have been noted as well as in the prevalence of prone positioning; blacks have a 2.5 times greater risk of SIDS and a prevalence of prone positioning of 21% compared with white infants who have a prone positioning rate of 11%.\textsuperscript{105,121,122} Despite the association between prone sleeping and SIDS, some parents continue to place their infant to sleep in the prone position. Many parents and health practitioners do not realize that the supine sleeping position is also associated with other health benefits, such as decreased rates of nasal congestion, otitis media, and fever before the age of 1 month.\textsuperscript{123}

The original 1992 recommendation from the AAP identified any nonprone position (supine or side) as reducing the risk for SIDS. Since then, however, studies have demonstrated that side sleeping is less stable, and has a higher risk for SIDS than the supine position.\textsuperscript{105,109,124}

Other postnatal factors associated with SIDS include soft sleep surfaces and loose bedding, overheating, and bed sharing.\textsuperscript{125-129} Polystyrene bead-filled pillows, soft pillows, quilts, comforters, sheepskin, and porous mattresses have been identified as risk factors for SIDS, particularly when placed under the sleeping infant.\textsuperscript{125} Overheating with clothing and blankets, as well as higher room temperatures also increase the risk. Bed sharing may lead to suffocation of an infant by an overlying adult, and the risk of SIDS associated with co-sleeping is greater when the adult is under the influence of alcohol or other mind-altering drugs.\textsuperscript{129}

Possible protective factors against SIDS have also been identified. A few retrospective studies have demonstrated a protective effect of breast-feeding; however, other analyses have failed to confirm the association after adjustment for confounding variables. Thus, the Task Force on Infant Sleep Position and Sudden Infant Death Syndrome does not recommend breast-feeding as a strategy for reducing SIDS.\textsuperscript{130} Other studies have demonstrated a lower incidence of SIDS among infants who use pacifiers, possibly by stinting of the airway. Conversely, the use of pacifiers is associated with an increased susceptibility to otitis media, an increased rate of dental malocclusion, and a shorter duration of breast-feeding. Additional outcome studies are therefore required before specific recommendations regarding pacifiers can be made.\textsuperscript{108,109}

The AAP Task Force on SIDS has made the following recommendations to reduce the risk of SIDS in the general population: (1) parents should place infants in the supine position for sleep (wholly on the back), and side sleeping is no longer recommended; (2) parents should not place infants to sleep on waterbeds, sofas, soft mattresses, or other soft surfaces; (3) soft
materials should not be placed in the infant’s sleeping environment; (4) smoking in pregnancy should be discontinued as smoking has proven to be a major risk factor for SIDS; (5) bed sharing and co-sleeping may be hazardous and should be avoided; (6) parents should consider offering a pacifier at nap time and bed time; (7) overheating should be avoided; (8) parents should avoid using commercially available devices to prevent SIDS as none of the devices has been adequately safety tested; (9) parents should not use home monitors to reduce the risk of SIDS as home monitoring has no effect on the incidence of SIDS; and (10) parents should place the infant in the non-prone position while the infant is awake to prevent positional plagiocephaly. 109

Pathophysiology and Etiology of Sudden Infant Death Syndrome. The pathophysiology of SIDS is multifactorial and includes genetic factors that may change an infant’s response to environmental or infectious stressors, maturational factors that affect the infant’s control of homeostatic mechanisms, and environmental factors, such as exposure to infection or being placed in the prone position. 105,108,131 This construct has been termed “the triple-risk theory,” 105,132,133 which suggests that when these factors combine, selected infants succumb to SIDS.

Genetic factors have not been fully defined, but recent data suggest multiple polymorphisms influence autonomic nervous system development and the ability of SIDS infants to respond. Arousability is affected by gestational and postnatal age, and the arousal threshold is significantly elevated at 2 to 3 months, when the rate of SIDS is highest. 134

Prone sleeping may further impair arousability. Prone sleep positions also cause a reduction in vasomotor tone with a lower resting blood pressure, a higher peripheral skin temperature, and a faster heart rate. A combination of sleep-induced reduction in vasomotor control with a reduction in central venous return and cardiac distension may trigger a brainstem-mediated bradycardia. Decreased central venous return compromises pulmonary perfusion and causes worsening hypoxia. 135,136 Prone positioning may exacerbate the rebreathing of exhaled gases trapped in soft bedding material, leading to hypercarbia and worsening hypoxia. 137,138

Diagnosis of Sudden Infant Death Syndrome. The diagnosis of SIDS is made at autopsy after postmortem evaluation fails to reveal another cause of death. Autopsies of SIDS victims demonstrate the effects of chronic hypoxemia, but no specific findings are pathognomonic of SIDS. 108,139-141

Guidelines are available for the diagnosis of SIDS by autopsy as well as for the on-scene investigation. 141-144 If a suspected SIDS death has occurred, a thorough investigation of the death scene may identify contributory factors, such as accidental asphyxiation or hyperthermia. Any findings suggestive of child abuse should be reported, although fewer than 5% of SIDS victims are discovered to have died of child abuse. However, in families with recurrent unexpected deaths, the estimated association increases to 55%. 103,145 Most investigations of the history, home circumstances, and postmortem examination are negative for child neglect or abuse. Child protection is rarely needed, but an investigation should be initiated if there is a recurrence of SIDS or an ALTE with a second baby. 103

Management of Sudden Infant Death Syndrome. In the management of a SIDS case, the death scene investigation should delineate the location and position of the infant, the room temperature, type of surface, presence of soft toys, pillows, bedding materials, and the general condition of the house.

Nonhospital Medical Considerations and Emergency Department Management of Sudden Infant Death Syndrome. Nonhospital medical care providers and emergency physicians may be involved in the resuscitation of infants who are apparent SIDS victims. In a study of apparent SIDS victims (cardiopulmonary arrest after being placed to nap by a caregiver) in Los Angeles and Orange Counties, California, all 113 infants with apparent SIDS ultimately died, 146 including the 30% of infants whose final diagnosis was not SIDS. Nonhospital management centers on the delivery of cardiopulmonary life support and rapid transport to the ED. These nonhospital providers may be faced with the complex decision to begin resuscitation and transport infants with possible SIDS or declare the infant with signs of death in the field. 146,147 Currently, no national guidelines are available for termination of resuscitation in the field for children; local practices dictate declaration of death without resuscitation as well as termination of resuscitation. Nonhospital providers generally feel uncomfortable in making the decision to terminate resuscitation, and patients are often transported to the ED for care.

Because CPR is unsuccessful in the majority of cases, the emergency physician must provide supportive care for the family. When the cause of death is unknown, appropriate samples (blood, urine, etc.) should be obtained. An autopsy should be performed on all SIDS deaths by a competent and experienced pathologist. 142

Psychosocial Considerations for Sudden Infant Death Syndrome. The emergency physician and pediatrician must address psychosocial considerations in any SIDS case. The physician should be direct when informing parents that their child has died. The word dead or died should be used instead of confusing euphemisms as passed on. 148-151 Parents universally experience intense guilt, and siblings may also have guilt over the loss of their brother or sister. Additionally, parents may further intensify the guilt by accusing one another of not taking adequate care of the infant. The police investigation may arouse suspicion in neighbors and friends, and leave the parents and caretakers socially alienated. The overall toll of guilt and social alienation is enormous, and the effects are manifested in increased rates of miscarriage, divorce, and infertility after a SIDS death. The outcome of SIDS for the family depends on the support they receive. Thus, the team approach, which includes the nurse, social worker, chaplain, emergency physician, and pediatrician, may provide comfort and information to the grieving family. The emergency physician and the pediatrician must recognize that they can play a pivotal role in helping the family to adjust to their loss, initiate the process of grieving, and educate the family about SIDS prevention. 152,153 The AAP and the American College of Emergency Physicians have outlined recommendations for emergency physicians in a joint policy statement entitled “Death of a child in the emergency department.” Recommendations for emergency physicians caring for families can be found in Table 8-2. 151

Health care providers may also experience guilt, self- reproach, and sadness after a SIDS death. Although the likelihood of survival for infants who present with SIDS is infinitesimally small, health care providers may require opportunities to openly express and work through these tumultuous emotions.

APPARENT LIFE-THREATENING EVENTS

Perspective

Epidemiology of Apparent Life-Threatening Event

Children with ALTE account for 0.8% of all ED visits of those younger than 1 year of age, and 2% of pediatric hospitalizations. Generally, children with ALTE are younger than 1 year, with a median age of 2 to 3 months. Most studies also demonstrate a male predominance as high as 2:1. 154,155
Recommendation for Emergency Physicians in Caring for Families of Children Who Have Died in the Emergency Department

Use a family-centered and team-oriented approach when a child dies in the ED. Provide personal, compassionate, and individualized support to families while respecting social, religious, and cultural diversity. Notify the child’s primary care physician of the death and, as appropriate, work with the primary care physician in follow-up of postmortem examination results. Organize resources and staff to provide a coordinated response to a child’s death, such as working with the primary care physician to notify subspecialty physicians of the death of their patient; identifying and reporting cases of child maltreatment; working with staff to provide resources to families for follow-up care and grief counseling; facilitating organ procurement; and assisting in critical stress management for prehospital and ED staff.

Distinguishing Principles of Disease

Pathophysiology and Etiology of an Apparent Life-Threatening Event

ALTE is a description of a characteristic clinical presentation; therefore, the pathophysiology of an ALTE has not been clearly defined. Children with ALTE pose a diagnostic and therapeutic challenge to emergency physicians because the cause of such events is diverse and ranges from minor to life-threatening. In addition, studies of children with ALTE reveal that in 50% of the cases, a definitive diagnosis will not be made.156,157 The AAP Committee on Child Abuse and Neglect outlines certain circumstances that should alert the emergency physician to the possibility of intentional suffocation in children with ALTE (Table 8-4).103 Injury associated with head trauma or child abuse may be difficult to distinguish in the absence of a reliable history. Intoxication, either accidental or intentional, as in Munchausen syndrome by proxy, can produce subsequent hypoventilation, hypoxia, cardiopulmonary arrest, and death.

In a retrospective study of 196 infants that presented with an ALTE, the discharge diagnoses included seizure (25%), GERD (18%), febrile convulsion (12%), bronchiolitis (9%), apnea (9%), pertussis (6%), choking (5%), upper respiratory tract infections (4%), cyanotic episode (2%), gastroenteritis (2%), asthma (1%), head injury (1%), feeding difficulties (1%), urinary tract infection (1%), and breath-holding (1%).100

Since GERD is physiologic and occurs in most infants, establishing the diagnosis of GERD does not prove that it is the cause of an ALTE.

An ALTE may be the first manifestation of an epileptic seizure, but the diagnosis is often difficult. A transient episode of apnea may be the only manifestation of a partial seizure, and the interictal electroencephalogram is characteristically normal. Seizures may be the cause for up to 11% of ALTEs, and a normal interictal electroencephalogram does not exclude seizures as the precipitating factor.162 QT prolongation has been associated with ALTE. Thus, an electrocardiogram is often recommended as an initial screen for differentiating an ALTE in the ED.162

Overall, the most common causes include GERD, seizure, and lower respiratory tract infection, accounting for 50% of the diagnoses associated with ALTE.

Management of an Apparent Life-Threatening Event

The infant who presents with a history of an ALTE may look well and act normally at the time of the evaluation by the nonhospital medical provider or the emergency physician. However, infants who are judged by nonhospital personnel to have choked, turned blue, or are showing other signs suggestive of a possible ALTE should be considered seriously ill and transported to the ED for evaluation.157 Fifty percent of children who present to the ED after an ALTE have an entirely
normal clinical examination, and the final diagnosis often correlates poorly with the presenting signs and symptoms, which often includes cyanosis, breathing difficulties, abnormal movements, loss of consciousness, vomiting, pallor, and choking.\textsuperscript{157}

In the ED, resuscitation must be the initial focus. Airway, breathing, and circulation should be stabilized. A complete history should be taken and a physical performed. If possible, the physician should obtain a detailed description of the infant at the time of discovery (especially the color and muscle tone of the infant), the duration of the episode, the resuscitation measures used, and the infant’s response to the resuscitation measures. Other questions that may be pertinent include the following: Was the infant awake or sleeping? Were there symptoms of airway obstruction? Does the infant have any history or symptoms suggestive of GERD? Did the event occur after feeding? Did the episode occur after vigorous crying (suggestive of breath-holding)? Is there any family history of SIDS, apnea, or unexplained sibling death?

During the physical exam, the physician should note the presence of stridor or wheezing. The skin should be examined for suspicious bruising (patterned bruises or truncal bruising suggestive of child abuse), the extremities for abnormalities (fractures, burns, healing wounds, or other signs of unusual injury), and the eyes for pupillary changes or retinal hemorrhages (shaken baby syndrome). A recent study demonstrated that a dilated fundoscopic examination in 128 patients who presented with an ALTE-detected retinal hemorrhages in 1.4\% of the patients and helped detect child abuse in 2.3\% of the patients.\textsuperscript{158} Thus, in addition to obtaining a detailed family and social history, it may be prudent to conduct a dilated fundoscopic exam in children who present to the ED after an ALTE.

The ED evaluation of children presenting with ALTE must be tailored to the child’s history and physical examination but often includes laboratory and radiographic studies. Laboratory evaluation may include complete blood count, serum glucose, electrolytes, blood and urine cultures if the child is younger than 1 month of age or febrile, a toxicology screen, and an electrocardiogram.\textsuperscript{159} The infants may also undergo a screen for inborn errors of metabolism, chest radiograph, computed tomographic scan of the head, and lumbar puncture depending on signs and symptoms at presentation, although few diagnostic tests are positive.\textsuperscript{160-163}

Inpatient evaluation often includes electroencephalogram, an evaluation for GERD (24-hour pH probe and barium esophagram), polysomnography for sleep disorders, and possibly flexible and rigid laryngoscopy.

The outcome of an ALTE depends on the underlying cause. In a retrospective patient review of 196 ALTE patients, there were no deaths.\textsuperscript{164} The follow-up revealed a high percentage of asthma and seizures, as well as GERD requiring Nissen fudoplication. Infants who survive an ALTE generally do well in follow-up. However, some rare complications do occur, including pulmonary edema, aspiration pneumonia, and neurologic sequelae secondary to hypoxia.\textsuperscript{166}

Based on the results of a study of 59 infants with ALTE, Claudius and Keens developed a clinical decision rule suggesting that infants younger than 1 month of age and those with recurrent ALTE should be admitted for evaluation, but other well-appearing children with ALTE may be discharged with close follow-up.\textsuperscript{167} Fu and Moon suggest other conditions under which it may be safe to discharge a patient with an ALTE, and these include the following: (1) the episode is brief, nonsevere, and self-resolving; (2) the cause is probably a nonprogressive condition such as GERD; and (3) the infant has no comorbidities and is well-appearing.\textsuperscript{154} It should be noted, however, that none of these proposed criteria has been adequately validated in clinical trials to determine which patients may be safely discharged from the ED. Multiple studies show that 84\% of cases of ALTE are admitted for evaluation and monitoring.

**Home Monitoring.** Monitoring devices measure chest wall movement and heart rate. Parents must learn about equipment maintenance, interpretation of alarms, and CPR. Technical support should be available to the parents 24 hours a day. Parents may misinterpret alarms when they sound, and the majority of alarms that parents felt required resuscitation were associated with normal electrocardiograms. Due to the lack of demonstrated efficacy and the frequency of false alarms, a great deal of controversy is associated with the use of home monitoring. In fact, the AAP Committee on Fetus and Newborn SIDS and home monitoring does not recommend home cardiorespiratory monitoring to prevent SIDS, since studies show that SIDS death is not reduced by home monitor use. Home monitors, however, may be warranted for premature infants with an ALTE, especially those younger than 43 weeks postmenstrual age or those with extreme episodes.\textsuperscript{168} Both pediatricians and emergency physicians should be consulted about monitor alarms. Admission to the hospital for further care may be prudent if the event was associated with the infant changing color or the infant required vigorous resuscitation.

**When Should Cardiopulmonary Resuscitation Be Discontinued?** Several factors determine the likelihood of survival after cardiac arrest, including the mechanism of the arrest (e.g., traumatic or asphyxial), location (out-of-hospital vs. in-hospital, ward vs. PICU), response (e.g., monitored vs. unmonitored, witnessed vs. unwitnessed), and underlying pathophysiology (e.g., cardiomyopathy, congenital defect, single-ventricle physiology, drug toxicity or metabolic derangement). Additionally, discontinuation of resuscitation in the nonhospital setting is further complicated because emergency medical service providers are not comfortable making this decision before transport to the hospital.\textsuperscript{157} These factors should all be considered before deciding to terminate resuscitative efforts.

Continuation of CPR has been considered futile beyond 15 to 20 minutes of CPR or when more than two doses of epinephrine are needed.\textsuperscript{169-181}

**Future Directions.** New epidemiologic initiatives, such as the National Registry for Cardiopulmonary Resuscitation for in-hospital cardiac arrests and the large-scale, multicenter National Heart, Lung, and Blood Institute Resuscitation Outcome Consortium for out-of-hospital arrests, are providing new data to guide our resuscitation practices and generate hypotheses for new approaches. Innovative technical advances, such as directive and corrective real-time feedback, can increase the likelihood of effective basic life support and skill sorely lacking in many resuscitative efforts today. In addition, team dynamic training and debriefing can rapidly identify weaknesses and improve operational performance.\textsuperscript{182} Simulation technology will be increasingly used for effective team training to provide excellent resuscitations\textsuperscript{183} and improve outcomes.

**KEY CONCEPTS**

- Excellent CPR is the foundation for successful resuscitation from cardiac arrest; without it all other subsequent interventions are rendered meaningless. The mantra for excellent CPR is: “Push Hard, Push Fast, Allow Full Chest Recoil, and Minimize Interruptions.” This “new emphasis” on CPR is intended to enhance CPR performance so that more lives can be saved.
- The thumb-encircling technique is recommended over the two-finger technique for chest compression in infants.
- Prospective and retrospective studies indicate that use of high-dose epinephrine in adults or children does not improve survival and may be associated with a worse neurologic outcome.
- Despite the dramatic decline in the incidence of SIDS in the past several decades, SIDS remains the leading cause of postneonatal mortality in the United States, accounting for one-third of all such deaths and is the third most common cause of infant deaths.
- Emergency physicians may play a key role in SIDS education and prevention. Parents must be taught the importance of the supine sleeping position, smoking cessation, and the elimination or avoidance of co-sleeping, overheating, and soft or loose bedding material.
- The team approach that combines the efforts of the nurse, social worker, chaplain, emergency physician, and pediatrician may help the family to adjust to their loss, initiate the process of grieving, and counsel the family about SIDS.
- Although the infant who presents with a history of an ALTE may look well and act normally at the time of the evaluation by the nonhospital medical provider or the emergency physician, these infants and children generally require admission and monitoring, as the final diagnosis and the presenting symptoms often correlate poorly.

CHAPTER 9
Neonatal Resuscitation

Suzan S. Mazor and Eileen J. Klein

PERSPECTIVE

Approximately 10% of newborns require some resuscitative assistance at birth, and approximately 1% require extensive resuscitative measures. Appropriate equipment and preparation, knowledge of neonatal physiology and response to stress, and skill in performing the necessary procedures are essential to successful resuscitation. Preparation for neonatal resuscitation requires an understanding of how it differs from pediatric and adult resuscitation, as follows:

1. Newborns have rapidly changing cardiopulmonary physiology, their own range of normal vital signs (Table 9-1), and unique responses to stress.
2. The approach to newborn resuscitation focuses almost entirely on respiratory, not cardiac, management.
3. Because of their small size, infants require special equipment.

PATHOPHYSIOLOGY

Transition from Fetal to Extraterine Life

The successful transition from the fetal to the extraterine environment requires two major cardiorespiratory changes: (1) removal of fluid from unexpanded alveoli to allow ventilation and (2) redistribution of cardiac output to provide lung perfusion. Failure of the development of either adequate ventilation or adequate perfusion leads to shunting, hypoxia, and ultimately reversion to fetal physiology.

In utero, the pulmonary alveoli are filled with pulmonary fluid. Removal of this fluid is partially accomplished by vaginal delivery, which compresses the fluid into the bronchi, trachea, and pulmonary capillary bed. Most pulmonary fluid is removed by the first few breaths; the amount of fluid removed depends on the forcefulness of these breaths. Expansion of alveoli requires the generation of high intrathoracic pressures and the presence of surfactant to maintain alveolar patency. The quality of the first few breaths is crucial to the establishment of adequate ventilation.

The fetal lung is poorly perfused. Because the pulmonary arterial bed is intensely vasoconstricted, the fetal lung receives only 40% of the right ventricular cardiac output; most of the right ventricular output is shunted from the pulmonary artery through the ductus arteriosus to the descending aorta. After the first few breaths, with exposure to diffused alveolar oxygen, pulmonary vascular resistance decreases. The fetal shunt through the ductus arteriosus reverses as systemic vascular resistance increases; then the shunt ceases by 15 hours of age as the ductus also constricts. This reversal of flow allows all right ventricular output to perfuse the lungs. If hypoxia or severe acidosis occurs, however, the muscular pulmonary vascular bed constricts again, and the ductus may reopen. The reinstitution of fetal circulation, with its attendant shunting, leads to ongoing hypoxia and is termed persistent fetal circulation. Resuscitation facilitates the first few breaths, prevents and reverses ongoing hypoxia and acidosis, and assists the newborn in the transition to extraterine life.

Neonatal Responses

Hypoxia

The newborn’s clinical response to severe hypoxia is unique. In utero or intrapartum asphyxia (pathologic lack of oxygen to the fetus before or during delivery) precipitates a sequence of events termed primary apnea and secondary apnea. After initial hypoxia, the infant gasps rapidly, followed by cessation of respirations (primary apnea) and a decreasing heart rate (HR). At this point, only simple stimulation and oxygen are needed to reverse bradycardia and assist the development of ventilation. With ongoing asphyxia, however, the infant takes several final deep, gasping respirations, followed by secondary apnea, worsening bradycardia, and decreasing blood pressure; in this case more vigorous and prolonged resuscitation is needed to restore ventilation and an adequate circulation. Apnea in the newborn should be assumed to be secondary apnea and treated rapidly with ventilatory assistance.

The presence of respiration may not ensure adequate ventilation. In addition, signs of hypoxia (e.g., cyanosis, lethargy, unresponsiveness) may have other causes. Bradycardia in the newborn (HR < 100 beats/min) almost always reflects inadequate ventilation and oxygenation. Bradycardia is a major indicator of hypoxia.

Hypothermia

The newborn’s inability to maintain body temperature (36.5–37°C) has severe physiologic consequences. The newborn cannot generate heat by shivering, cannot retain heat because of low fat stores, and has a relatively large surface-to-volume area. In addition, the newborn is at risk for heat loss because of a high metabolic rate, wet amniotic fluid covering, and exposure to a relatively cool environment, especially in contrast to intrauterine temperature. The body temperature easily decreases, and low body temperatures can lead to meta-
bolic acidosis, increased oxygen consumption, hypoglycemia, and apnea.2,8 Some studies have suggested that selective cerebral hypothermia in asphyxiated infants may protect against brain injury, but there is not enough evidence to implement such a therapy until further study is performed.9-13 Currently, cerebral hypothermia in asphyxiated infants may protect against cerebral hypothermia after resuscitation of infants with possible asphyxia.1

**Hypoglycemia**

The newborn is at risk for developing hypoglycemia (defined as glucose level < 40 mg/dL if the newborn weighs > 2.5 kg or < 30 mg/dL if < 2.5 kg) when stressed because of poor glycogen stores and immature liver enzymes. Hypoglycemia is common in premature or small-for-gestational-age infants and in infants born to diabetic mothers. It also develops in response to respiratory illness, hypothermia, asphyxia, and sepsis. Hypoglycemia may be asymptomatic or may cause an array of symptoms, including apnea, color changes, respiratory distress, lethargy, jitteriness, seizures, acidosis, and poor myocardial contractility.14 Low blood glucose has been associated with adverse neurologic outcomes in both animal and clinical studies.15,16

### INDICATIONS FOR RESUSCITATION

Any infant born outside of the controlled environment of the delivery room should be considered in need of resuscitation.17 Minimal intervention may be required, but a standardized approach as described in this chapter should be followed. Some specific conditions increase the likelihood that resuscitation will be required. Premature infants pose a special problem because of their immature lungs and susceptibility to hypothermia. Adequate ventilation and warming are essential to a successful resuscitation.

The presence of meconium in the amniotic fluid at delivery indicates that the infant has been stressed before delivery and warrants special consideration in resuscitation. When delivered, a nonvigorous infant with meconium in the amniotic fluid must have the trachea suctioned before other steps in resuscitation to prevent aspiration of meconium.

Medications given to the mother or illicit drugs taken before delivery can lead to respiratory depression in the newborn. Maternal opioid administration or opioid use should be considered in any newborn with isolated respiratory depression. Naloxone reverses respiratory depression caused by opioids. Naloxone may have a shorter half-life than the original maternal opioid; so the neonate should therefore be monitored closely for recurrent apnea or hypoventilation, and subsequent doses of naloxone may be required.1 Use of naloxone may precipitate acute withdrawal in infants who have prolonged intrauterine opioid exposure.18,19 Therefore, in infants whose mothers may have had long-term opioid exposure, support of ventilation may be preferable to reversal using naloxone.

Hemorrhage caused by abruptio placentae, placenta previa, trauma, or other complications can lead to respiratory depression and shock. Hemorrhage is one of the few situations in which fluid resuscitation is required. No reliable set of parameters has been identified for newborns who should not receive resuscitative efforts.20 Currently, resuscitation is not recommended for neonates with confirmed gestational age less than 23 weeks; those with birth weight less than 400 g; and those with confirmed anencephaly, trisomy 13, or trisomy 18.1,21,22 In the out-of-hospital setting or in the emergency department, every attempt should be made to stabilize the neonate until it is clear that attempted or continued resuscitation would not improve the patient’s chance of survival. Infants with no signs of life (no heart beat and no respiratory effort) after 10 minutes of resuscitation show either a high mortality or severe developmental delay. After 10 minutes of continuous and adequate resuscitative efforts, discontinuation may be justified if there are no signs of life.23,24 Few situations require deviations from the approach described here. The presence of meconium may require intervention after delivery. Other anatomic anomalies require special care and include diaphragmatic hernia, meningomyelocele, abdominal anomalies (e.g., gastroschisis, omphalocoele), and upper airway obstructive lesions (e.g., bilateral choanal atresia, Pierre Robin sequence).

### SPECIFIC DISORDERS

#### Meconium Aspiration

Meconium in the amniotic fluid is a sign of in utero distress, and the presence of thick or particulate meconium before or at delivery should raise concern about the potential for aspiration. Aspiration of meconium and its consequences can be avoided by rapid intervention to avoid aspiration. Previous recommendations included suctioning meconium from the infant’s airway after delivery of the head but before delivery of the shoulders (intrapartum suctioning). However, evidence from a large multicenter trial did not show benefit from intrapartum suctioning.25 Therefore, current recommendations no longer advise routine intrapartum suctioning for infants born to mothers with meconium-stained fluid. Decision to perform endotracheal intubation with tracheal suctioning after delivery of the infant should be made based on the vigor of the infant, rather than on the consistency of the meconium (e.g., thick or particulate vs. thin). Infants with meconium-stained fluid and with any of the following are candidates for tracheal suctioning: (1) absent or depressed respirations, (2) poor muscle tone, or (3) HR less than 100 beats/min.21,22,26 In such newborns, a meconium aspirator should be attached to the endotracheal tube (ETT) and connected to wall suction at 100 mm Hg or less. The ETT is withdrawn as suction is being applied. The ETT with meconium aspirator serves as the ideal suction catheter. Because of its narrower width, a suction catheter placed in the ETT does not suction meconium effectively. Reintubation and suction should be repeated until the meconium clears. Two passes are usually sufficient. When these steps are completed, the resuscitation should continue, beginning with the steps at the top of the neonatal flow algorithm (Fig. 9.1).

#### Anatomic Anomalies

The neonate should be intubated as soon as possible if a prenatal diagnosis of diaphragmatic hernia was made or if a diaphragmatic hernia is diagnosed on chest radiograph. Bag-mask
obstruction; if not, intubation may be necessary. It is technically difficult to intubate a patient with Pierre Robin sequence, so a laryngeal mask airway (LMA) may be placed instead. Consultation with anesthesiology may be needed.

**PREPARATION**

To maximize the effectiveness of resuscitation, the emergency department should have a prestocked drug pack, standardized equipment (Box 9-1), and staff familiar with newborn resuscitation. The pediatric Broselow Emergency Tape has a section that can be used to determine equipment size and drug dosages for newborn resuscitation for infants weighing greater than or equal to 3 kg. It is crucial to use universal precautions and to wear gown, gloves, and eye protection during neonatal resuscitation. For adequate preparation, the heat source must be turned on early, and the resuscitation table must be warm when the newborn is placed on it. Equipment of proper size is essential, especially respiratory equipment because it is most likely to be

![Neonatal flow algorithm](Figure 9-1). Neonatal flow algorithm. *Endotracheal intubation may be considered at several steps. (From American Heart Association, American Academy of Pediatrics, Pediatrics 117:e1029, 2006. © Copyright 2006 American Academy of Pediatrics.)
used, and ventilation is the key to most resuscitative efforts. Appropriately sized self-inflating devices and ventilation masks decrease complications from overventilation and prevent injury or inability to ventilate because of improper mask fit.

If available, additional information may be helpful in preparing for resuscitation (Box 9-2). The estimated gestational age provides information about possible prematurity and associated complications. Multiple births require more equipment and personnel, and the newborns are at greater risk for prematurity and its complications. Meconium present in the amniotic fluid may require suctioning of the neonate’s trachea after delivery. A history of maternal vaginal bleeding increases the likelihood of hypovolemic shock and respiratory distress in the newborn. A history of medication administration or drug use may provide clues to the cause of respiratory depression in the neonate.

**MANAGEMENT**

An organized approach is key to successful resuscitation outside and inside the delivery room. The American Heart Association and the American Academy of Pediatrics have published a neonatal flow algorithm (see Fig. 9.1)—a stepwise approach to neonatal resuscitation. These steps are discussed in this section.3

**Dry, Warm, Position, Suction, Stimulate, Assess Need for Further Intervention**

To prevent complications caused by hypothermia, all newborns should be dried off as soon as possible after delivery and placed under a radiant heat source. Wet blankets should be replaced after drying with dry, preferably warm blankets. Next, the neonate should be positioned to maximize air entry and avoid obstruction of airflow. Because of the infant’s relatively large occiput and anterior airway, an open airway is best achieved with the neck in slight extension. The slightly extended position is best accomplished by placing a rolled diaper or small towel under the infant’s shoulders. Placement under the neck is not useful, and a towel that is too large and under the shoulders leads to hyperextension at the neck and possible airway occlusion.

If meconium is present and the newborn has poor respirations, poor tone, or bradycardia (HR < 100 beats/min), the trachea should be suctioned with an ETT before any other intervention. If no meconium is present, the newborn may be suctioned with bulb or mechanical suction (<100 mm Hg wall suction). The mouth should be suctioned first, followed by the nose. The mouth is suctioned first to avoid aspiration of material if the infant takes in a breath after suctioning of the nose. Vigorous or deep suctioning can lead to a vagal response, with subsequent bradycardia, or to apnea, and should be avoided.31

Usually these measures adequately stimulate the infant to breathe effectively and may be the only measures needed to resuscitate a newborn. If adequate respirations are not present at this point, stimulation of the infant is needed; this is best done by flicking the soles of the feet and rubbing the back. It is important to avoid stimulation that is too vigorous because it does not aid in initiation of respirations and may stress the newborn. If stimulation is not effective in initiating respirations, bag-mask ventilation is required followed by intubation if necessary.

The Apgar score, comprising HR, respiratory effort, muscle tone, reflex irritability, and color, has been used as a prognostic indicator in newborns (Table 9-2). The Apgar score is not useful in resuscitation management, however.32 Muscle tone and reflex irritability do not aid in the assessment of the newborn during resuscitation.32 HR, respiratory effort, and color are the important indicators of hypoxia and should be monitored continuously. Further resuscitative efforts are required if respiratory effort is insufficient, HR is less than 100 beats/min, or central cyanosis is present.

**Oxygen, Ventilation, Intubation**

Any infant who is cyanotic or appears to be in respiratory distress (grunting, nasal flaring, tachypnea) should be given 100% oxygen. If the infant is apneic, appears to be in severe respiratory distress, has an HR of less than 100 beats/min, or has central cyanosis despite oxygen administration, bag-mask ventilation (with a manometer, if available) should be initiated. Although resuscitation with 100% oxygen is recommended, especially for hypoxia, more recent studies support the effectiveness of room air if 100% oxygen is not available for bag-mask ventilation.31,22,33-36 The initial breaths require higher pressure (30–40 mm Hg) to remove lung fluid and to get the chest to rise. Subsequent breaths generally require 20 mm Hg.

1. Gown, gloves, and eye protection (universal precautions)
2. Blankets (to warm and dry infant)
3. Radiant warmer
4. Bulb syringe
5. Suction and suction catheters (French #5, #8, and #10)
6. Self-inflating bags (450 and 750 mL)
7. Masks ( premature, newborn, and infant sizes)
8. Laryngoscope with straight blades (No. 0 and 1)
9. Endotracheal tubes with styles (2.5, 3, and 3.5 mm)
10. Scissors and tape to stabilize endotracheal tube
11. Meconium aspirator
12. Umbilical catheters (French #3.5 and #5)
13. Hemostats, sterile drapes and gloves, povidone-iodine solution, scalpel, umbilical tape, suture, and three-way stopcock for umbilical vessel catheterization

**Box 9-2 Maternal History Questions**

1. What is the estimated gestational age?
2. Is this a multiple gestation?
3. Is meconium present?
4. Is there a history of vaginal bleeding?
5. Were medications given or drugs taken?

---

![Image](image-url)
Excessive pressures, more than is needed to achieve chest rise should be avoided since barotraumas may result. The primary measure of adequate initial ventilation is a prompt improvement in HR. An appropriately sized mask with a good seal (covering the mouth and nose, but not the eyes), proper positioning of the infant, and use of appropriate pressure to attain chest wall movement are essential for effective ventilation. The newborn should be ventilated at 40 to 60 breaths/min, unless blood gases dictate otherwise. If bag-mask ventilation is required for more than 2 minutes, an orogastric tube should be placed to prevent respiratory compromise from stomach distention.

Endotracheal intubation may be indicated at several points during neonatal resuscitation: when tracheal suctioning for meconium is needed, if bag-mask ventilation is ineffective or prolonged, when chest compressions are performed, and for extremely low-birth-weight infants or infants with anatomic anomalies (e.g., diaphragmatic hernia). Box 9-1 lists the equipment needed for endotracheal intubation. Confirmation of proper ETT placement should include detection of expired carbon dioxide.

Acute deterioration (bradycardia, decreased oxygen saturation) after intubation should suggest one of the following problems (DOPE): 1.

1. Dislodgment: The ETT is no longer in the trachea (right main stem bronchus or esophagus).
2. Obstruction: Secretions are obstructing airflow through the ETT.
3. Pneumothorax
4. Equipment: Oxygen is not being delivered to the patient (check equipment).

If the patient acutely deteriorates after intubation, the equipment should be checked quickly; if no explanation is obvious, the patient should be extubated and ventilated with a self-inflating resuscitator (bag-mask ventilation device). Time should not be wasted adjusting or suctioning the ETT if the patient is bradycardic. If unequal breath sounds are present after extubation, or if the patient is not improving with effective ventilation, needle aspiration of the chest should be considered for treatment of a possible pneumothorax.

The LMA has been shown effective for ventilating full-term newborns; however, there are limited data on LMA use in preterm infants.

### Chest Compressions

Bradycardia (HR < 100 beats/min) is the major indicator of hypoxia. Most infants respond promptly to effective ventilation with 100% oxygen. If a neonate has an HR of less than 60 beats/min despite oxygen and adequate ventilation (good air movement and chest rise) for at least 30 seconds, chest compressions should also be provided. Chest compressions should be performed at a rate of 90/min, with 30 breaths/min for a total of 120 events/min. The preferred method for performing chest compressions is as follows:

The fingers of both hands encircle the chest and support the back. The thumbs of both hands are placed side by side or one over the other on the sternum just below the nipple line. The depth of compression is one third the anteroposterior diameter of the chest.

Respirations, HR, and color should be reassessed about every 30 seconds, and coordinated chest compressions and ventilation should continue until the spontaneous HR is greater than or equal to 60 beats/min.

### Medications

Few neonates require the use of medications during resuscitation. Medications are indicated for bradycardia or asystole that does not respond to effective ventilation and chest compressions, and for hemorrhage (maternal, fetal, or placental) that requires fluid resuscitation. Naloxone may be needed for respiratory depression caused by maternal ingestion of opioids before delivery.

The only medications that should be used during the early phase of neonatal resuscitation are oxygen, epinephrine, and volume expanders (Table 9-3). Albumin has been removed as an initial resuscitation drug but may be used in the postresuscitation phase. Dopamine should be reserved for prolonged resuscitation. Naloxone should be used only after the neonate is adequately ventilated. Sodium bicarbonate should not be used in most resuscitations; it may be beneficial in the rare instance of a prolonged resuscitation when metabolic acidosis has been documented and ventilation is adequate.

No current evidence supports the use of atropine or calcium in neonatal resuscitation.

Vascular access is a challenge in neonatal resuscitation. The preferred route of immediate vascular access is the umbilical vein because it is easily identified and cannulated. Because of

potentially serious complications (infection, portal vein thrombosis), the umbilical vein cannula should be removed immediately after stabilization after other access (e.g., umbilical artery catheterization) has been attained. Other routes include peripheral veins and the femoral vein. Intraosseous access can be problematic in neonates (especially premature infants) because of bone fragility and the small size of the intraosseous space. If vascular access cannot be achieved, some drugs (e.g., lidocaine, epinephrine, atropine) can be given through the ETT. The medication should be injected directly into the ETT, followed by several positive-pressure ventilations.

Oxygen

The first resuscitation medication that should be used is 100% oxygen. Indications for oxygen use include central cyanosis and respiratory distress (nasal flaring, grunting, tachypnea, apnea).

Epinephrine

Epinephrine is indicated for asystole, and for an HR less than 60 beats/min despite effective ventilation with 100% oxygen and chest compressions. Although epinephrine may be given by ETT, the preferred administration route is intravenous (IV). The IV dose is 0.01 to 0.03 mg/kg or 0.1 to 0.3 mL/kg of 1:10,000 solution. Repeat doses may be given every 3 to 5 minutes. If the endotracheal route is used, doses of 0.01 or 0.03 mg/kg will likely be ineffective. While access is being obtained, administration of up to 0.1 mg/kg through the ETT may be considered, but the safety and efficacy of this practice have not been evaluated.

Naloxone

Respiratory depression induced by opioids given or taken within 3 to 4 hours of delivery can be reversed with naloxone. If respiratory depression is present, and if it is unclear whether the mother took opioids before delivery, reversal with naloxone may be attempted. The dose is 0.1 mg/kg IV, IO, SQ, or intramuscularly (IM). Administration of naloxone by ETT is not recommended in newborn resuscitation. The duration of action of naloxone is 1 to 4 hours, depending on route of administration. Repeat dosing may be necessary, and the patient should be monitored carefully. Naloxone is not always needed in a newborn with respiratory depression. It may precipitate withdrawal seizures in an infant born to a drug-addicted mother. The priority of care is support of ventilation with bag-mask device and intubation, if necessary. Naloxone should be considered only after ventilatory support is achieved.

Glucose

Hypoglycemia should be considered in a neonate undergoing resuscitation. Hypoglycemia is diagnosed with a rapid bedside glucose or serum glucose measurement. Treatment is indicated only for documented hypoglycemia: glucose less than 40 mg/dL in a full-term infant (>2.5 kg) and less than 30 mg/dL in a premature infant (<2.5 kg). Hypoglycemia is treated with 2 to 4 mL/kg of 10% dextrose in water (D10W). Higher concentrations of glucose (e.g., 25% dextrose in water, D25W) are hyperosmolar and should be avoided. Repeat glucose measurement should be obtained 10 to 20 minutes after glucose administration.

Volume Expanders

Volume expanders are indicated when acute bleeding is evident with signs of hypovolemia (pallor despite oxygenation, weak pulses with a good HR, poor response to resuscitation), or the newborn appears to be in shock. Volume expanders include whole blood (Rh-negative type O blood crossmatched with the mother’s blood), normal saline, or Ringer’s lactate solution. Whole blood is preferred in the setting of significant blood loss but may be difficult to obtain quickly. Normal saline and Ringer’s lactate (e.g., isotonic crystalloid solutions) should be readily available and may be considered the fluid of choice overall for volume expansion. Expanders are given in small IV boluses of 10 mL/kg over 5 to 10 minutes. When resuscitating premature infants, rapid administration of volume expanders should be avoided, as this has been associated with intraventricular hemorrhage. Higher volume (e.g., 20 mL/kg) fluid boluses are recommended for older infants. Boluses may be repeated several times, guided by patient assessment. The use of albumin 5% with saline is currently not recommended for the initial resuscitation.

Dopamine

Dopamine is indicated only when signs of shock (e.g., poor peripheral perfusion, thready pulses) are still present despite adequate volume replacement. Given as a continuous infusion beginning at 5 µg/kg/min, dopamine may be increased to 20 µg/kg/min as necessary.

DISPOSITION

Early consultation with a neonatologist can assist in the resuscitation and postresuscitation phases of care. When the neonate has been stabilized, monitoring of oxygenation, ventilation, perfusion, temperature, and glucose must continue. Preparations should be made for transport of the newborn to a neonatal intensive care unit. A transport team with personnel skilled in neonatal resuscitation should be employed. Ideally, before transport, parents should see and touch (and hold if medically appropriate) their newborn.

Fever in the Adult Patient

Frederick C. Blum

**PERSPECTIVE**

Epidemiology

Fever is part of the presenting complaint in 6% of all adult (aged 18–65) visits to the emergency department (ED), 10 to 15% of all elder (older than 65 years) patient visits, and 20 to 40% of all pediatric visits. Morbidity and mortality rates vary dramatically with age. Younger adults with fever usually have benign self-limited disease with less than 1% mortality. The challenge in this group is to identify the rare meningitis or septic conditions when confronted with a predominance of self-limited viral and focal bacterial diseases. Patients older than 65 years, or those with chronic disease who present with fever, represent a group at high risk for serious disease. Morbidity and mortality rates in this group are significant. Between 70 and 90% are hospitalized, and 7 to 9% die within 1 month of admission. Infection is the most common cause of fever in these patients, and most of these infections are bacterial in nature. Three body systems: the respiratory tract, the urinary tract, and the skin and soft tissue, are the target for more than 80% of these infections. The relative mortality and morbidity for any given infection are much higher in the geriatric population. For example, elders are at 5 to 10 times greater risk for urinary tract infections and 15 to 20 times for appendicitis. Even viral illnesses that are generally not fatal, such as influenza, can be highly lethal in elder persons.

Pathophysiology

Body temperature is normally controlled within a narrow range by the preoptic area of the hypothalamus. This range is usually between 36.0 and 37.8°C (96.8–100.4°F). There is a circadian rhythm within this range, with lower temperatures in the morning and higher temperatures in the late afternoon. Fever occurs when this normal range is reset to a higher value. Fever is typically defined as a core temperature greater than 38.0°C (100.4°F). Fever should not be confused with hyperthermia. Hyperthermia is an elevation of the temperature related to the inability of the body to dissipate heat. Almost all cases of temperatures higher than 41.0°C (105.8°F) are due to hyperthermia rather than to fever.

In the anterior hypothalamus, neurons directly sense the blood temperature. Temperature is subsequently controlled by a combination of vasomotor changes, shivering, changes in metabolic heat production, and behavioral changes.

Fever may be produced by a number of endogenous and exogenous substances referred to as pyrogens. Endogenous pyrogens include a variety of cytokines released by leukocytes in response to infectious and inflammatory and neoplastic processes. Exogenous pyrogens include a large number of bacterial and viral products and toxins. Toxins induce fever by stimulating cells of the immune system to release endogenous pyrogens. These cytokines, such as interleukin-1 (IL-1), IL-6, tumor necrosis factor, and interferon, travel to the hypothalamus and induce the production of prostaglandin E2 (PGE2).

PGE2 raises the set point of the temperature range by a combination of effects including peripheral vasoconstriction, increased metabolic heat production, shivering, and behavioral changes that conserve heat. Fever is maintained as long as the levels of endogenous pyrogens and PGE2 are high. Cyclooxygenase inhibitors, such as aspirin, decrease fever by blocking the production of PGE2. Age, malnutrition, and chronic disease may also blunt the febrile response.

Moderate elevations of the body temperature may serve to aid the host defense by increasing chemotaxis, decreasing microbial replication, and improving lymphocyte function. Elevated temperatures directly inhibit the growth of certain bacteria and viruses.

Fever also results in certain increased costs to the host including increased oxygen consumption, metabolic demands, protein breakdown, and gluconeogenesis. These costs are particularly problematic in elders, who typically have a smaller margin of reserve for any given body system. It is well established that the ability to develop fever in elders is somewhat impaired. Older individuals also are known to have lower baseline temperatures than younger adults. It has not been proved that treatment of fever with antipyretics has a beneficial effect on outcome or prevents complications.

The initial step in the process of fever is the resetting of the thermostatic set point in the hypothalamus to a higher temperature while actual body temperature remains normal. This mismatch of the thermostat with the “sensed” body temperature causes the patient to feel chilled (chills). If the chills are reported to a caregiver and the skin is touched or the temperature is taken, it is usually noted to be normal or minimally elevated. The patient remains chilled until the body temperature rises. At this point, the patient feels euthermic (but may feel fatigued or ill), but to the caregiver, the skin temperature or thermometer reading is now elevated. This sequence of chills followed by febrile illness is the basis of the (incorrect) popular belief that getting chilled leads to infection (classically pneumonia). When the thermostatic set point is reduced to normal, the patient suddenly feels hot and...
sweats until the body temperature falls to match the (now normal) set point.

**DIAGNOSTIC APPROACH**

**Differential Considerations**

The complete differential diagnosis for the patient presenting to the ED with fever is extensive. The major infectious and noninfectious causes are summarized in Table 10-1 and Box 10-1, respectively. The vast majority of serious causes are infectious in origin. Immediate threats to life result from decompensated shock (usually septic), respiratory failure (related to shock or pneumonitis), or central nervous system infection (meningitis). Some critical noninfectious causes of fever also exist (see Box 10-1), but these are relatively rare and frequently do not occur with fever as the primary symptom.

**Rapid Assessment and Stabilization**

Patients with life-threatening signs and symptoms, including significant alterations in mental status, respiratory distress, and cardiovascular instability, may require rapid, vigorous treatment. Prompt airway management and initiation of monitoring, intravenous access, fluid resuscitation, supplemental oxygen, and respiratory support are often necessary despite incomplete information concerning the cause of the fever. Sustained temperatures above 41.0°C are rare but can be damaging to neural tissue and require rapid cooling (e.g., misting, fans, cooling blankets).

In the younger, otherwise healthy patient with fever, immediate threats to life such as toxic or septic shock, meningitis, meningococcemia, and peritonitis should be considered and treated empirically.

In the older, chronically ill population with fever, most of the serious illnesses originate from infections in the respiratory tract, the genitourinary tract, and the skin and soft tissues. Meningitis, although less common, can also be a significant cause of morbidity and mortality in this group.

**Pivotal Findings**

Although the differential diagnosis of fever is broad, most of the treatable causes are of infectious origin. Up to 85% of these may be diagnosed by careful history and physical examination alone. Age and the presence of underlying medical conditions can substantially influence the evaluation and subsequent decision-making regarding management.

In younger and otherwise healthy adults, self-limited, localized bacterial infections or benign systemic viral infections are usually the cause of their fever. The challenge with this group is to identify the rare life-threatening illness, such as meningococcemia, meningitis, or systemic methicillin-resistant *Staphylococcus aureus* (MRSA) infection.

In the older or chronically ill population, fever is frequently a sign of severe illness. Usually, the cause is infectious. Eighty percent have respiratory infections, urinary tract infections, or soft tissue infections as the cause. Infections such as meningitis, cholecystitis, appendicitis, and diverticulitis may arise with atypical signs and symptoms in elderly or immunosuppressed patients. In this population, subtle changes in behavior may be the only sign of severe infection. Abnormal vital signs, especially significant tachypnea and hypotension, may portend a complicated and severe course. Seventy-five percent of the cases of functional decline in nursing home patients are due to infection.5,7
The onset of the fever, its duration and magnitude, and any associated symptoms help identify possible causes and severity of illness. Localizing symptoms such as dysuria or productive cough are especially helpful. The timing of the fever and its patterns may implicate certain diseases (e.g., malaria). Recent or remote travel, chronic illnesses, past surgeries, hospitalizations, and treatment modalities may raise the suspicion of exotic or nosocomial infections. The presence of cardiac valves or any prosthetic or indwelling device may be critical to the diagnosis. With the emergence of community-acquired MRSA, it is important to seek a history of skin infections in close family members or other close contacts. MRSA should also be considered in military personnel, prisoners, and persons involved in competitive sports that involve close contact.9,10 Also important is a list of all the patient’s medications, including any antipyretic medication. Family members are frequently an important source of information in elder and very young patients. They are often the first to notice a functional decline in the patient, such as difficulty ambulating, anorexia, decreased activity, or new urinary incontinence. A decline in mental status in the older patient may be the only clue to the presence of significant infection. The patient’s baseline mental function must rely on the reports of others who know the patient well.

Atypical symptoms are common in elder patients. Pneumonia or urinary tract infection in the older patient may be heralded by only a change in mental status, difficulty ambulating, or some other functional decline. Dysuria, frequency, and flank pain often are absent entirely in elders with urinary tract infection. Patients with pneumonia may inconsistently present with productive cough or shortness of breath. Other frequent but nonspecific symptoms include anorexia, weight loss, weakness, lethargy, nausea, and recurrent falls.8,9 A history of cancer with recent chemotherapy or radiation therapy may be a clue to leukopenia or other immunodepressed states.4

**Physical Examination**

The presence and magnitude of fever is an important element of the examination, but the elder, very young, or chronically ill patient may not mount a febrile response to significant infection. Temperatures may fluctuate, and rechecks may be necessary.

Rectal temperatures are the most accurate. Axillary and tympanic temperatures often are unreliable. Oral temperatures may be transiently distorted by recent ingestion of hot or cold liquids, smoking, or hyperventilation. Rectal temperatures are typically 0.7 to 1.0°C higher than oral temperatures.

Fever is inconsistently associated with tachycardia and tachypnea. The heart rate may increase by 10 beats/min for each 0.55°C (1°F) degree rise in temperature. Relative bradycardia may be caused by medication such as beta-blockers, but can suggest factitious or drug-related fevers, thyroid fever, brucellosis, or leptospirosis. Frank bradycardia may occur with rheumatic fever, Lyme disease, viral myocarditis, and endocarditis. The respiratory rate may increase 2 to 4 breaths per minute per degree Celsius. More significant tachypnea may be due to respiratory infection or the acidosis related to shock.

In many patients, the examination is directed by the patient’s localization of symptoms. The head and neck examination focuses on treatable foci of infection such as otitis media, sinusitis, pharyngitis, peritonsillar abscess, retropharyngeal abscess, and dental infections. A muffled, “hot potato” voice with severe sore throat may be a clue to adult epiglottitis or upper airway abscess. Fundoscopy rarely may reveal evidence of disseminated candidiasis, miliary tuberculosis, endocarditis, toxoplasmosis, or leukemia.

The neck is examined for lymphadenopathy, masses, or thyroid pathology (thyromegaly or mass). Nuchal rigidity or pain on forward flexion of the neck is assessed but may not be prominent in the very young, or in a debilitated or elder patient, even if meningitis is present. Conversely, cervical arthritis or Parkinson’s disease may cause preexisting nuchal rigidity.

The lungs are examined for rales, pleural rubs, or dullness to percussion. Localized rales or rhonchi may be more subtle clues to the presence of pneumonia. The presence of concomitant chronic obstructive pulmonary disease or congestive heart failure, as well as poor respiratory effort, may hamper the diagnosis of pneumonia in elders. The heart is examined for pericardial rubs or new murmurs.

The abdominal examination may be deceptively benign in older patients, patients with diabetes, or patients taking immunosuppressives or steroids.10 When indicated by history or other findings, a rectal examination is performed to check for evidence of enteritis, perirectal abscess, or prostatitis. The external genitalia examination may reveal evidence of Bartholin’s abscess, urethral or vaginal discharge, or evidence of epididymitis or orchitis.

Females with appropriate symptoms should have a pelvic examination to evaluate for pelvic inflammatory disease or tubo-ovarian abscess. The skin and extremities should be evaluated for rash, petechiae, joint inflammation, or evidence of soft tissue infection. In the absence of trauma, tenderness over the long bones or the spine may be evidence of osteomyelitis or neoplastic processes. Elders and bedridden patients should be checked for the presence of pressure sores or decubitus ulcers.3

**Ancillary Testing**

The two most important ancillary tests, especially in elder patients, are urinalysis and chest radiography. Chest radiographs are often helpful in the diagnosis of pulmonary infection but may be difficult to interpret in the patient with concurrent chronic obstructive pulmonary disease, congestive heart failure, dehydration, or other chronic lung disease. The urinalysis, although not foolproof, is highly accurate for urinary tract infection, especially in men. Although the white blood cell count is almost universally used in the evaluation of febrile patients, it lacks the sensitivity and specificity to be of discriminatory value. The white blood cell count may incorrectly indicate serious infection when none is present or may be normal in the presence of life-threatening infection.11 Other indirect tests of infection and inflammation, such as the erythrocyte sedimentation rate, are also plagued with irregular sensitivity and poor specificity and should be used sparingly. Gram’s stain of appropriate specimens may be helpful, and cultures may be ordered, although the results do not influence emergency evaluation and treatment. With the emergence of MRSA, it has become increasingly important to obtain cultures from soft tissue skin abscesses in patients considered at risk for MRSA infection. In elder or chronically ill patients with fever of unknown source, blood and urine cultures are frequently appropriate. Outpatient blood cultures should rarely, if ever, be done. A patient ill enough to require blood cultures generally requires hospitalization and empirical antibiotic coverage. Cerebrospinal fluid evaluation should be considered when mental status changes or if headache, meningismus, or other unexplained neurologic symptoms are present and cannot be clearly accounted for by infection outside the central
nervous system. Thyroid function studies may be helpful when thyroid storm is suspected.

Plain films of the abdomen are rarely indicated or helpful. Abdominal computed tomography (CT) is helpful if appendicitis, diverticulitis, cholecystitis, or intra-abdominal abscess is suspected. Ultrasonography may be helpful in the patient with potential cholecystitis.

Cranial CT scanning may be indicated prior to lumbar puncture in patients with focal neurologic findings or an embolic source, such as suspected endocarditis, to exclude mass lesions such as tumor or brain abscess. This test should not delay antibiotics in patients with suspected meningitis.

Other ancillary testing is directed by the findings of the history and physical examination.

DIFFERENTIAL DIAGNOSIS

The differential diagnoses of infectious causes of fever are summarized in Table 10-1. The differential diagnoses of non-infectious causes of fever are listed in Box 10-1.

EMPIRICAL MANAGEMENT

Patients with temperatures greater than 41.0°C require prompt and vigorous treatment with antipyretics and possibly external cooling measures. Temperatures above this range can result in damage to neuronal tissue. There is no evidence for improved outcome by routine use of antipyretic therapy, such as acetaminophen, in patients without extreme temperature elevation, but it is not harmful, and patients often feel better when their temperature declines. Achieving a normal or near-normal temperature is not necessary as a criterion for discharge, however. Patients with signs and symptoms of shock require prompt and vigorous treatment (see Chapter 4). Patients with evidence of respiratory failure from shock or pneumonia require ventilatory support. Soft tissue infections of the head and neck may compromise the airway because of mechanical obstruction. These may require acute intervention to provide a secure airway.

In many cases, early empirical antibiotic therapy is appropriate. The choice of antibiotics is based on the likely cause of the fever as well as concomitant conditions such as absolute neutropenia and end-stage renal disease. If a specific infection is identified, antibiotic therapy should be specific to that infection. In the absence of a clear source of infection, broad-spectrum coverage of gram-positive and gram-negative aerobic and anaerobic bacteria is indicated.

DISPOSITION

Localized bacterial infections can most frequently be treated with outpatient oral antibiotics. Relatively young, healthy patients with systemic viral illness can be treated as outpatients. These illnesses are often accompanied by vomiting and poor oral intake, and treatment in the ED with antipyretics, antinausea medications, and intravenous hydration may help prepare the patient for a successful outpatient course.

When no clear infection is identified in older patients or those with chronic illness such as diabetes or chronic renal failure, admission to the hospital often is necessary to further elucidate the possible causes of the presentation. In this subset of patients, a diligent search for evidence of bacterial infection is required. Also, admission to an inpatient unit or ED observation unit may be advisable when fever or other systemic symptoms accompany a suspected MRSA infection. In patients with unexplained severe febrile illness, blood and urine cultures and broad-spectrum antibiotics are indicated to treat possible life-threatening infection, until a specific disease process or pathogen is identified. Indwelling devices, such as percutaneous intravenous access ports, frequently require culture and may need to be removed. Neutropenic patients with fever require prompt treatment with broad-spectrum parenteral antibiotics pending results of cultures. Patients with unstable vital signs or life-threatening infections may require admission to a special care unit if they cannot be adequately stabilized in the ED prior to admission.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Weakness is a subjective term that can be used to describe many symptoms that can relate to a variety of disease states. *Webster’s Dictionary* definition for weak is “lacking strength, deficient in physical vigor, not able to sustain or exert much weight, pressure, or strain.” However, when a patient uses the term weakness, he or she might be describing symptoms beyond the loss of muscle power. Malaise, frailty, fatigue, pain, dizziness, and alteration of mental status might all be described as weakness.

This chapter focuses on the evaluation and treatment of patients complaining of the acute onset of generalized, diffuse, and symmetrical weakness. Discussion regarding chronic neurologic conditions, localized weakness, space-occupying lesions, and traumatic injury can be found elsewhere.

**Epidemiology**

No research data are currently available specifically related to the presenting complaint of “weakness” in the emergency department (ED). Because this complaint can originate from derangements in multiple organ systems, it is difficult to get a true estimate of its frequency in the ED setting.

Acute neuromuscular weakness is a relatively rare entity. Polio has been eradicated in Western Europe and North America, and there has been a dramatic decrease in the incidence of this disease worldwide (1187 cases in 2007 per the World Health Organization). The most common cause of acute symmetrical weakness in industrialized countries is Guillain-Barré syndrome, with an annual incidence of 2 cases per 100,000 in the United States. To put this in perspective, the incidence of diabetes mellitus is 740 cases per 100,000. New infectious causes of acute symmetrical weakness have emerged in the past few decades including West Nile virus and HIV.

**Pathophysiology**

The key differentiation is whether the patient has actual, quantitative, muscle weakness. If so, the nervous system is involved, often with dysfunction of the motor unit. In contrast, the complaint of weakness in the absence of decreased strength on examination suggests a disease process outside of the nervous system. These two broad categories of weakness will be examined in turn.

**Neuromuscular Weakness**

Muscle contraction is the result of a series of signals that originate in the cerebral cortex. Upper motor neurons (UMN) originate in the motor strip, anterior to the central sulcus, and travel in the pyramidal system. They descend the spinal column in the lateral corticospinal tract on the side opposite their origin in the brain. The UMN then synapses with the lower motor neuron (LMN) in the anterior horn of the spinal cord, which in turn carries the signal to the muscle bundle. The LMN (peripheral nerve) releases acetylcholine into the synaptic cleft, which then depolarizes the motor endplate and results in muscle contraction. This series of events depends on the presence of myelin insulating the nerves, the function of calcium and sodium channels, and the presence of acetylcholinesterase. Neuromuscular weakness can be caused by lesions or derangements at any level of this cascade of events.

**Non-neuromuscular Weakness**

A patient’s complaint of weakness often stems from a non-neuromuscular cause. The patient’s age, underlying health status, current symptom complex, and examination findings help narrow the differential diagnosis. Infectious, cardiovascular, endocrine, metabolic, and toxicologic causes of the patient’s complaint need to be considered.

**Diagnostic Approach**

**Pivotal Findings**

**History**

A clear description of the symptoms is crucial to clarifying whether the patient is experiencing neuromuscular weakness. Does the patient describe a decrement in function? For example, is the patient unable to climb stairs because of leg weakness or because of shortness of breath and fatigue? The former case is likely to be due to neuromuscular weakness; the latter may be related to compromised cardiovascular function or another systemic process.

It is important to obtain the time course of symptoms, severity, and their progression or worsening. The distribution (proximal, distal, generalized) of weakness, fluctuations in function, and alleviating or aggravating factors (activity, rest) are also
important factors. The presence or absence of bladder and bowel dysfunction, sexual dysfunction, paresthesias or altered sensation, and muscle pain or spasm should also be elicited. Recent history of infectious illness, trauma, new medications, exposure to toxins, alcohol and drug use should also be considered. Table 11-1 lists a few of the serious causes of acute neuromuscular weakness with their distinguishing characteristics and management.

The patient’s age, comorbidities, and overall vigor or frailty should be taken into account. A thorough review of organ systems should be performed. The presence or absence of fever, infectious symptoms, fatigue, chest discomfort, dyspnea, malaise, abdominal discomfort, alteration of bowel habits, especially melena or hematohcezia, and headache should be elicited. Careful medication review, especially of diuretics, beta-blockers, and psychotropic medications, may suggest
Neuromuscular
ED
HISTORICAL
Fever, hypotension, tachycardia, or tachypnea may provide clues regarding the source of the patient’s complaint (Table 11-2). If severe weakness is present, an assessment of the patient’s ability to maintain the airway and the adequacy of respiration is indicated (Fig. 11-1).

The neurologic exam should focus on clarifying if the patient is experiencing true loss of strength along with the distribution of the deficits (Table 11-3). A complete examination, including cranial nerves, and gait, where possible, is helpful. The motor exam should be systematic and thorough. Muscle bulk, strength, tone, and the presence or absence of abnormal movements should be noted. Sarcopenia (age-associated loss of muscle mass and function) is normal in the older adult. In this situation, the loss of power is uniform in all limbs. Walking on heels, toes, and in tandem is a good test of strength as well as coordination and proprioception. Gait apraxia has a wide differential and should prompt investigation for cerebellar abnormality; normal pressure hydrocephalus should be considered in the patient who has simultaneous incontinence and decreased cognitive function. Fine muscle fasciculations typically point to an LMN disorder, whereas spasticity, greater in the flexors than extensors, is seen in UMN lesions.

Examination

Sarcopenia (age-associated loss of muscle mass and function) is normal in the older adult. In this situation, the loss of power is uniform in all limbs. Walking on heels, toes, and in tandem is a good test of strength as well as coordination and proprioception. Gait apraxia has a wide differential and should prompt investigation for cerebellar abnormality; normal pressure hydrocephalus should be considered in the patient who has simultaneous incontinence and decreased cognitive function. Fine muscle fasciculations typically point to an LMN disorder, whereas spasticity, greater in the flexors than extensors, is seen in UMN lesions.

Ancillary Testing

Patients presenting with weakness can have myriad underlying abnormalities. Although testing will be guided by the history and exam, virtually all patients require a complete blood count to evaluate for anemia or blood loss and serum electrolytes, glucose, and creatinine. An electrocardiogram...
Any patient who appears to have respiratory compromise or for whom Guillian-Barré syndrome or myasthenia gravis is possible should undergo bedside spirometry. A forced vital capacity (FVC) of less than 10 to 12 mL/kg or a negative inspiratory force (NIF) of less than 20 cm H2O is an indication for respiratory support. An arterial blood gas test for carbon dioxide tension or capnography may also be helpful.

### Differential Diagnosis and Initial Management

The differential diagnosis of weakness is very broad, and at times, a definitive diagnosis is impossible in the span of an ED visit. Ensuring appropriate disposition and follow-up is particularly important in these patients.

In a patient with neuromuscular weakness, the respiratory drive is preserved, but the ability to ventilate adequately can be impaired and the patient may complain of dyspnea. Patients with rapid progression of weakness may require early airway intervention and mechanical ventilation. Warning signs of worsening respiratory status include the inability to lift the head, ineffective cough, alteration of the voice, and difficulty controlling secretions. As a crude measure of vital capacity, the patient’s inability to count to 20 in a single exhalation suggests that the FVC is compromised; when the patient can only count to 10, the FVC can be estimated at 1 L and preparations to intubate should be made. About 30% of patients with Guillian-Barré syndrome require mechanical ventilation, and several studies have demonstrated that an elective, controlled intubation leads to better outcomes in terms of ventilation-associated pneumonia and total time on the ventilator.

Patients with neuromuscular weakness increase their respiratory rate to compensate for low tidal volumes, and the PaCO2 is maintained within the normal range. If the patient develops muscle fatigue or increased muscle weakness, the PaCO2 will rise and respiratory failure can occur quickly. In this situation, intubation, usually using a rapid sequence technique, is indicated. Succinylcholine should be avoided when a progressive denervation syndrome is suggested. The up-regulation and redistribution of acetylcholine receptors on denervated myocytes that occurs with succinylcholine can lead to significant hyperkalemia with administration of this drug (see Chapter 1).

In addition, autonomic instability in these patients can make intubation challenging; the physician should anticipate the possibility of labile blood pressures and bradycardia. Bradycardia responds to atropine administration, and the blood pressure should be closely monitored but not necessarily treated as it can fluctuate rapidly.

### Special Situations

**Myasthenia Gravis: Myasthenic Crisis versus Cholinergic Crisis**

Myasthenia gravis is discussed in detail in Chapter 106. *Myasthenic crisis* refers to a rapid worsening of neuromuscular function with respiratory compromise. It occurs in approximately 15% of patients with this disease and can be triggered by infection (= 30% of cases), change in medications, metabolic derangement, or physical stress; a third of the time no cause is found. A crisis can be precipitated by a recent change in the dose of the patient’s anticholinesterase inhibitor, recent initiation or tapering of corticosteroids, and recent initiation of several commonly used medications (aminoglycoside and quinolone antibiotics, beta-blockers, and antiarrhythmic agents). Myasthenic crisis is associated with prolonged hospitalization and intubation periods of 1 to 3 weeks.

Figure 11-2. Differential diagnosis algorithm: Weakness.
Cholinergic crisis results from an excess of cholinesterase inhibitor medication that produces a flaccid muscle paralysis and generalized weakness. Respiratory failure may be present with or without other cholinergic symptoms.

These two forms of crisis can be difficult to distinguish but are managed similarly with a focus on airway protection and ensuring adequate ventilation. Potential triggers for the crisis should be sought, and because many of these patients are on immunosuppressive medications, infection should be strongly considered. An urgent neurology consultation may be helpful, and an edrophonium challenge test may be performed if a myasthenic crisis is suggested (see Chapter 106).

Older Adults and Frailty

In the older adult with a complaint of weakness, an accurate history can be difficult to obtain. In addition, comorbidities and polypharmacy can often complicate the presentation in these patients.

Frailty is a biologic syndrome defined by decreased reserve and resistance to stressors and is an independent predictor of future functional decline, falls, hospitalization, and mortality. Hallmarks of this syndrome include generalized muscle weakness, poor endurance, weight loss, low physical activity, and slow gait speed. The prevalence of frailty in community-dwelling persons older than age 65 is approximately 7% and it increases with age and female gender.

Older adults with disability, frailty (as measured by their functional status, grip strength, and ability to ambulate), and comorbid chronic illness are at high risk for poor outcome after the ED visit. A thorough evaluation with attention to potential life-threatening conditions and a low threshold for admission and further evaluation is warranted in this population.

One year post-ED visit with hospitalization, mortality in this population is in the range of 25%.

**DISPOSITION**

Most patients presenting to the ED with a complaint of weakness have a non-neuromuscular cause for their complaint. The history, exam, and results of ancillary testing dictate treatment and disposition of these patients.

Those patients who present with acute symmetrical neuromuscular weakness require a thorough evaluation with particular attention to their airway and ventilation. Disposition decisions should be made in conjunction with neurology consultation, and admission to the intensive care unit for close respiratory monitoring should be considered.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
**Perspective**

An estimated 7.5 million patients with dizziness are seen each year in ambulatory care settings. It is one of the most common principal complaints in the emergency department. Benign paroxysmal positional vertigo, felt to be caused by loose particles in the semicircular canals, is the most common cause of vertigo with an incidence estimated to be 107 cases per 100,000 population per year. Dizziness in older persons is associated with a variety of cardiovascular, neurosensory, and psychiatric conditions and with the use of multiple medications. Among patients older than 60 years, 20% have experienced dizziness severe enough to affect their daily activity. In a study of 1000 outpatients, dizziness was the third most common complaint. Vertigo is defined more clearly as a sensation of disorientation in space combined with a sensation of motion. In 1921, Bárány published the first detailed description of benign paroxysmal positional vertigo.

A complaint of “dizziness” is an imprecise term. The emergency department physician may believe that the patient will be difficult to interview and that the condition will be problematic to diagnose and treat. But in reality, most of these patients have an organic basis for symptoms that can be successfully identified and treated. The diagnostic process is consistently based on two basic concepts: deciding whether the patient has true vertigo and, if vertigo exists, deciding whether the cause is central or peripheral.

**Pathophysiology**

The maintenance of equilibrium and awareness of the body in relationship to its surroundings depend on the interaction of three systems: visual, proprioceptive, and vestibular. The eyes, muscles, joints, and otic labyrinths continuously supply information about the position of the body. Visual impulses, mediated through the higher brain centers, provide information about body position in space. Impulses from proprioceptors of the joints and muscles supply data about the relative positions of the parts of the body. Impulses from the neck are of special importance in relating the position of the head to the rest of the body. The sense organs of the visual, vestibular, and proprioceptive systems are connected with the cerebellum by way of the vestibular nuclei in the brainstem. Any disease that interrupts the integration of these three systems may give rise to symptoms of vertigo and disequilibrium.

The vestibular apparatus helps maintain head position and stabilize head movement. It is housed in the inner ear, or labyrinth, which lies embedded in the petrous portion of the temporal bone, where it is vulnerable to trauma; blood-borne toxins; and infections in nearby structures, including the middle ear and meninges. The vestibular apparatus consists of three semicircular canals with their cristae and two otolithic structures: the utricle and saccule. The semicircular canals provide information about movement and angular momentum; the otoliths provide information about the orientation of the body with respect to gravity.

The semicircular canals are paired structures that normally respond to motion in a symmetrical manner. With inner ear disease, the resting discharge or the discharge stimulated by motion can be altered in one ear. This alteration produces asymmetrical responses and results in the perception of vertigo. Freely moving debris within the semicircular canals can produce positional vertigo as the debris moves under the influence of gravity.

Impulses leave the vestibular apparatus by the vestibular part of the acoustic nerve (cranial nerve VIII), enter the brainstem just below the pons and anterior to the cerebellum, and proceed to the four vestibular nuclei of the brainstem and to the cerebellum. From there, impulses travel along two pathways that contribute to the clinical manifestations of vertigo: the medial longitudinal fasciculus and the vestibulospinal tract. In individuals with healthy vestibular systems, these connections allow the eyes to compensate for body movement in different directions and to maintain a visual axis that is stable with respect to the environment.

Nystagmus occurs when the synchronized vestibular information becomes unbalanced. Typically, it results from unilateral vestibular disease, which causes asymmetrical stimulation of the medial and lateral rectus muscles. This unopposed activity causes a slow movement of the eyes toward the side of the stimulus, regardless of the direction of deviation of the eyes. The cerebral cortex then corrects for these eye movements and rapidly brings the eyes back to the midline, only to have the process repeated.

By convention, the direction of nystagmus is denoted by the direction of the fast “cortical” component. Nystagmus caused by vestibular disease tends to be unidirectional and horizontal. If the nystagmus is vertical, a central lesion (either brainstem or cerebral) is usually the cause.

The vestibular nuclei send information to the lateral vestibulospinal tract, where they connect with motor neurons that supply the muscles of the extremities. This phenomenon explains the false steps or other body movements made by people with a defective vestibular apparatus who are
Causes of Vertigo

Characteristics

A diagnostic approach

Differential Considerations

Patients use the term dizzy to describe a variety of experiences, including sensations of motion, weakness, fainting, light-headedness, unsteadiness, and depression. To clarify the picture, it is often helpful to have patients describe the sensation without using the word dizzy. True vertigo may be defined as a sensation of disorientation in space combined with a sensation of motion. There is a hallucination of movement either of the self (subjective vertigo) or the external environment (objective vertigo). Descriptions of light-headedness or feeling faint are more consistent with presyncope. The differential diagnosis for these patients should include dysthyrhythmias, myocardial infarction, sepsis, hypovolemia, drug side effects, and pulmonary embolism. For some patients, dizziness is simply a metaphor for malaise, representing a variety of other causes, such as anemia, viral illness, or depression. The primary focus of this chapter is to review the evaluation of the vertiginous patient.

If the patient has true vertigo, the clinician must determine whether the cause is a peripheral lesion (e.g., of the inner ear) or a central process, such as cerebrovascular disease or a neoplasm. In most cases, peripheral disorders are benign, and central processes have more serious consequences. Occasionally, as in the case of a cerebellar hemorrhage, immediate therapeutic intervention is indicated. Acute suppurative labyrinthitis is the only cause of peripheral vertigo that requires urgent intervention. Box 12-1 lists causes of vertigo and identifies the peripheral, central, and systemic diagnoses. Table 12-1 summarizes the different characteristics of peripheral and central vertigo.

Pivotal Findings

History

The medical history is the most important source of information. A first key question is, “Does true vertigo exist?” Does the patient have a sensation of disorientation in space or a sensation of motion? The sensation of spinning usually indicates a vestibular disorder. Some nausea, vomiting, pallor, and perspiration accompany almost all but the mildest forms of vertigo. The presence of these symptoms without vertigo suggests a different cause. The labyrinth has no effect on the level of consciousness. The patient should not have an associated change in mentation or syncope. A sensation of imbalance often accompanies vertigo, but true instability, disequilibrium or ataxia makes a higher likelihood of a central process.

Because nystagmus accompanies acute vertigo, it is often helpful to ask members of the patient’s family if they have noted any unusual eye movements during the dizzy spells. This question is especially important in children unable to offer a concise history. Occasionally, the patient may be able to describe a flickering or oscillating visual field immediately after a change in position, such as rolling over in bed. In addition, interviewing family and other witnesses can often uncover evidence suggesting seizures, syncope, or imbalance unrelated to feelings of vertigo.

The time of onset and the duration of vertigo are important clues to the cause. Episodic vertigo that is severe, lasts several hours, and has symptom-free intervals between episodes sug-

</table>
suggests a peripheral labyrinth disorder. Vertigo produced primarily by a change in position also suggests a peripheral disorder. Vestibular neuritis and benign positional vertigo fit this pattern.

The presence of auditory symptoms suggests a peripheral cause of the vertigo, as in middle and inner ear problems, or a peripheral cause that progresses centrally, such as an acoustic neuroma. The abnormally hearing ear is usually the side of end-organ disturbance. Progressive unilateral hearing loss of several months’ duration may be the earliest symptom of an acoustic neuroma. Tinnitus occurs in most patients with acoustic neuroma and, along with vertigo, is what often prompts patients to seek medical attention. Hearing loss, vertigo, and tinnitus form the characteristic triad of Ménière’s disease.

Are there associated neurologic symptoms? The patient or family members should be questioned about the time of onset of ataxia or gait disturbances. Ataxia of recent and relatively sudden onset suggests cerebellar hemorrhage or infarction in the distribution of the posterior inferior cerebellar artery or the superior cerebellar artery. The salient feature of chronic cerebellar disorders is a slowly progressive ataxia. True ataxia may be difficult to discern from the unsteadiness that occurs when a patient with significant vertigo attempts to walk.

Vertiginous symptoms are common after head injury. The presence of recent head or neck trauma should be explored because vertiginous symptoms are common after both. Head injury can cause vertigo occasionally from intercerebral injury and more commonly from labyrinth concussion. Neck injury can cause vertigo from strain of muscle proprioceptors. In addition, vertebral artery injury has been seen resulting from activities such as chiropractic manipulation and even hair shampooing with marked hyperextension in a salon.

It has clearly been shown that isolated vertigo can be the only initial symptom of cerebellar and other posterior circulation bleeds, transient ischemic attacks (TIAs), and infarction. One study showed that emergency physicians often did not make the correct diagnosis in patients with validated strokes or TIAs that presented with only vertigo. Risk factor assessment and symptom patterns can be extremely helpful in deciding which patients warrant imaging and admission. Older age, male sex, hypertension, coronary artery disease, diabetes mellitus, and atrial fibrillation put patients at higher risk. In addition, frequent episodes lasting only minutes or prolonged episodes of a day or more are more often associated with central processes. A recent retrospective study showed emergency physicians often failed to chart triggers and duration of dizziness, information that could potentially lead to increased likelihood of a more serious cause of symptoms.

Past Medical History. Many medications have direct vestibulotoxicity. The most commonly encountered are the aminoglycosides, anticonvulsants, alcohols, quinine, quinidine, and minocycline. In addition, caffeine and nicotine can have wide-ranging autonomic effects that may exacerbate vestibular symptoms. The history of past and present illnesses should be explored, with specific questioning about the existence of diabetes, drug or alcohol use, and the risk factors mentioned earlier.

Physical Examination

Vital Signs. In some cases, pulses and blood pressure should be checked in both arms. Most patients with subclavian steal syndrome, which also can cause vertebrobasilar artery insufficiency, have pulse or systolic blood pressure differences between the two arms.

Head and Neck. Carotid or vertebral artery bruits suggest atherosclerosis. The neck is auscultated along the course of the carotid artery from the supraclavicular area to the base of the skull.

Vertigo can be caused by impacted cerumen or a foreign object in the ear canal. Accumulation of fluid behind the eardrum as a result of a middle ear infection may cause mild vertigo, as can occlusion of the eustachian tubes associated with an upper respiratory tract infection. A perforated or scarred eardrum may indicate a perilymphatic fistula, especially if the history includes previous trauma.

Examination of the eyes is key in assessing a patient with vertigo or disequilibrium. The focus is on any pupillary abnormalities indicating third cranial nerve or descending sympathetic tract involvement or optic disk signs of early increased intracranial pressure. Extraocular movements should be assessed carefully. Relatively subtle ocular movement abnormalities can be the only clue to a cerebellar hemorrhage. A sixth cranial nerve palsy ipsilateral to the hemorrhage may result from early brainstem compression by the expanding hematoma. Internuclear ophthalmoplegia is recognized when the eyes are in a normal position on straight-ahead gaze, but on eye movement the adducting eye (cranial nerve III) is weak or shows no movement while the abducting eye (cranial nerve VI) moves normally, although often displaying a coarse nystagmus. This finding indicates an interruption of the medial longitudinal fasciculus on the side of the third cranial nerve weakness. It indicates brainstem pathology and is virtually pathognomonic of multiple sclerosis.

Abnormal nystagmus is the cardinal sign of inner ear disease and the principal objective evidence of abnormal vestibular function. In nystagmus, the patient has difficulty maintaining the conjugate deviation of the eyes or has a postural control imbalance of eye movements.

The abnormal jerk nystagmus of inner ear disease consists of slow and quick components. The eyes slowly “drift” in the direction of the diseased, hypoactive ear, then quickly jerk back to the intended direction of gaze. Positional nystagmus, induced by rapidly changing the position of the head, strongly suggests an organic vestibular disorder. The characteristics of nystagmus are one of the most valuable tools for distinguishing peripheral from central causes of vertigo (Table 12-2).

Positional Testing. If nystagmus is not present at rest, positional testing can be helpful in determining its existence and characteristics. In the Hallpike maneuver, the patient is moved quickly from an upright seated position to a supine position, and the head is turned to one side and extended (to a head-down posture) approximately 30° from the horizontal plane off the end of the stretcher. The eyes should be observed for nystagmus and the patient queried for the occurrence of symp-

toms. This test should be repeated with the head turned to the other side. Positive elicitation of symptoms and signs to one side or the other generally indicates vestibular pathology on that same side. This test should be performed with caution if verteobasilar insufficiency (VBI) is suggested because sudden twisting movements theoretically might dislodge atheromatous plaques (Fig. 12-1).

**Neurologic Examination.** The presence of cranial nerve deficits suggests a space-occupying lesion in the brainstem or cerebellar pontine angle. The corneal reflex is a sensory cranial nerve V and motor cranial nerve VII circuit. Its diminution or absence can be one of the early signs of an acoustic neuroma. Vertigo caused by eighth cranial nerve involvement is likely to be accompanied by a unilateral hearing loss. Patients cannot hear a tuning fork when it is held alongside the affected ear, but they can hear it when it is held against the mastoid process. Involvement of the eighth cranial nerve suggests an acoustic tumor. Seventh cranial nerve involvement causes facial palsy that affects the entire side of the face. In supranuclear facial paralysis, the forehead is spared because these muscles receive bilateral cortical innervation.

The patient should be evaluated specifically for evidence of cerebellar dysfunction. This examination must be performed in bed and standing because truncal ataxia may be occult on testing of limbs in bed and may become obvious only when the patient has to sit, stand, or walk unaided. Dysmetria is the inability to arrest a muscular movement at the desired point. Dysmetria should be assessed using finger-to-finger/finger-to-nose pointing, and dysdiadochokinesia (an inability to perform coordinated muscular movement smoothly) is assessed with rapid alternating movements. The gait must be evaluated when the patient gives a history suggesting ataxia, although examination may be impossible during an attack of vertigo. Any marked abnormality (e.g., consistent falling or a grossly abnormal gait) should suggest a central lesion, especially in a patient whose vertiginous symptoms have subsided. The main features of a cerebellar gait are a wide base (separation of legs), unsteadiness, irregularity of steps, tremor of the trunk, and lurching from side to side. The unsteadiness is most prominent on arising quickly from a sitting position, turning quickly, or stopping suddenly while walking. Patients with gait ataxia cannot perform heel-to-toe walking.

**Ancillary Testing**

Most routine laboratory testing is not helpful in the evaluation of a vertiginous patient. A finger-stick blood glucose test should be performed in most cases because hypoglycemia can present as vertigo. Blood counts and blood chemistries are sometimes helpful when it is difficult to distinguish whether “dizziness” is vertigo or near-syncope. An electrocardiogram should be obtained if there is any possibility of myocardial ischemia.

**Radiologic Imaging.** If cerebellar hemorrhage, cerebellar infarction, or other central lesions are suggested, emergent computed tomography (CT) or magnetic resonance imaging (MRI) of the brain is indicated. MRI, when available, has become the diagnostic modality of choice when cerebellar processes other than acute hemorrhage are possible. MRI is particularly useful for the diagnosis of acoustic neuromas and for sclerotic and demyelinating lesions of the white matter, as seen in multiple sclerosis. Acute vertigo by itself does not usually warrant urgent CT or MRI in all patients, particularly patients in whom a clear picture of peripheral vertigo emerges. But as mentioned earlier, many studies strongly support the use of imaging in patients of advanced age or at risk for cerebrovascular disease.

Conventional angiography or magnetic resonance angiography can be used in cases of suspected VBI to document the presence of vascular disease. It is used most often in patients with changing neurologic signs and symptoms, suggesting impending posterior circulation occlusion.

Audiology and electronystagmography are helpful in the follow-up evaluation of a vertiginous patient. Audiology can locate the anatomic site of a lesion causing vertigo. Electro-nystagmography is a collection of examinations that, when abnormal, suggest vestibular dysfunction but do not yield the specific diagnosis.

**DIFFERENTIAL DIAGNOSIS**

The differential diagnosis for other peripheral, central, and systemic causes of vertigo is large (see Box 12-1). More detailed information is given on selected causes in Table 12-3, including the most common peripheral causes of true vertigo: benign positional vertigo, vestibular migraine, Ménière’s disease, and vestibular neuritis.

**Diagnostic Algorithm**

Most cases of vertigo are of peripheral origin and are not usually life-threatening. The diagnostic approach must focus on identifying entities that either immediately or in the near future can lead to death or significant morbidity (Fig. 12-2).

**Management**

Management is based on an accurate diagnosis that distinguishes the serious central causes of vertigo from the less serious, albeit more debilitating, peripheral causes (Fig. 12-3). Any suggestion of cerebellar hemorrhage should warrant immediate imaging with CT or MRI and neurosurgery consultations. VBI should be considered in any patient of advanced age or at high risk of cerebrovascular disease with isolated, new-onset vertigo without an obvious cause. Because of the possibility of progression of new-onset VBI in the first 24 to 72 hours, hospital or observation unit admission and consid-

Peripheral
Attacks: sudden, severe, usually seconds or minutes
Nystagmus: horizontorotary, worsened by head position
No neurologic findings
Auditory findings may be present

Central
Attacks: gradual, mild, usually continuous for weeks or months but can be sudden, severe and seconds or minutes with vascular causes
Nystagmus: horizontal, rotary, or vertical
Little change with head position
Neurologic findings usually present
No auditory findings

BPPV
Short-lived, positional episodes probably caused by stray otoconial particles

Ménière’s
Tinnitus
Hearing loss
Attacks in clusters
Long symptom-free intervals

Vestibular neuronitis
Severe vertigo for days
Mild persistent positional vertigo
No auditory symptoms

Acoustic neuroma
Peripheral cause that can become central
Vertigo, hearing loss, tinnitus

Labyrinthitis

Acute suppurative
Signs of toxicity
Toxic patient
Severe vertigo
Hearing loss

Serous
No signs of toxicity
Milder symptoms
Inflammatory response to nearby infections

Toxic
Hearing loss
Tinnitus
Medication exposure

Chronic
Chronic symptoms
Secondary to fistula

Vertebrobasilar insufficiency
 Usually associated neurologic abnormalities
More likely in the elderly and those with history of cardiac or cerebrovascular disease

Cerebellar hemorrhage
Severe vertigo, headache, vomiting, ataxia

Hypoglycemia

Head/neck trauma

Multiple sclerosis

Vertebrobasilar migraine

Vertebrobasilar insufficiency

Figure 12-2. Diagnostic algorithm for dizziness and vertigo. BPPV, benign paroxysmal positional vertigo.

The treatment of acute attacks of vertigo caused by peripheral disorders is symptomatic. Intravenous diazepam in 2- to 5-mg doses is extremely effective in stopping vertigo. It has a sedative effect that acts on the limbic system, the thalamus, and the hypothalamus. Outpatient treatment with diazepam can be continued at doses of 5 to 10 mg three times daily.

The neurons involved in vestibular reactions are mediated by acetylcholine. Anticholinergic drugs or antihistamines with anticholinergic activity are extremely useful in treating vertigo. Meclizine hydrochloride (Antivert) is usually prescribed as 25 mg every 8 hours, but has a wide therapeutic margin and can be taken much more frequently to control symptoms. Diphenhydramine hydrochloride (Benadryl), 25 to 50 mg every 6 to 8 hours, and dimenhydrinate (Dramamine, Gravol) are also effective, but are more sedating than meclizine. Either drug also can be given intravenously. Transdermal scopolamine has shown disappointing results for treatment of peripheral vertigo but may be considered a third-line or fourth-line option. Promethazine hydrochloride (Phenergan), 25 mg orally or rectally every 6 to 8 hours, is effective because of its strong antiemetic and mild anticholinergic properties; it also can be used intravenously in doses of 12.5 to 25 mg. Buccal

prochlorperazine (Compazine, Stemetil) also has been shown to be a safe and effective treatment for vertigo. Avoidance of stimulants (e.g., caffeine, pseudoephedrine, nicotine) may ease symptoms in some cases. In addition, canalith repositioning procedures, such as the Epley and Semont maneuvers, have been shown to be extremely effective in treating benign paroxysmal positional vertigo.\(^\text{19-21}\) The Epley maneuver involves sequential movement of the head into four positions, staying in each position for approximately 30 seconds, as demonstrated in Figure 12-4. One study has even shown these maneuvers have resulted in long-term efficacy in successful symptom treatment.\(^\text{22}\)

One of the most useful tools the physician has is patient reassurance. Most patients with vertigo have self-limited disease processes that have a specific organic cause. By combining patient education and reassurance with judicious use of medications, the treatment of a dizzy patient can be rewarding for the patient and the physician.

### DISPOSITION

Documented or suggested cerebellar hemorrhage or infarction, VBI, and acute bacterial labyrinthitis require workup and hospitalization. In patients older than age 55 years, particularly patients with vascular disease, admission for observation and imaging of cerebral vasculature is often warranted. Most younger patients with peripheral causes of vertigo can be discharged from the emergency department after symptoms are controlled. Some patients may have such severe symptoms (e.g., vomiting, inability to walk) despite a trial of medication that they require admission for intravenous hydration and observation. All discharged patients should receive primary care; neurology; or a follow-up consult with an ear, nose, and throat specialist. This follow-up is especially important for possible cases of acoustic neuroma and toxic labyrinthitis.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The term confusion connotes an alteration in higher cerebral functions, such as memory, attention, or awareness. Confusion is a symptom, not a diagnosis. Clinical jargon includes “altered mental status,” “delta MS” (change in mental status), “altered mentation,” and “change from baseline.” Additionally, the ability to sustain and focus attention is impaired. Symptoms of confusion may fluctuate, as may the level of consciousness. Implicit in the definition is a recent change in behavior. Chronic mental status changes such as dementia typically have a different clinical chronology. Other forms of altered mentation include states of diminished alertness on the coma spectrum; these presentations may result from some of the same pathophysiologic processes causing confusion and are discussed in Chapter 15. Confusion may range in severity from a mild disturbance of short-term memory to a global inability to relate to the environment and process sensory input. This extreme state is termed delirium. Delirium has two subtypes: hyperactive and hypoactive. Hyperactive delirium is characterized as an acute confusional state associated with increased alertness, increased psychomotor activity, and disorientation and is often accompanied by hallucinations. In hypoactive delirium (sometimes referred to as quiet delirium), the confusional state is present but the patient has a reduction in alertness and behavior. Confusion has many causes, and an orderly approach is necessary to discover the causative diagnosis.

Epidemiology

Physicians underestimate the incidence of confusion in patients. Often, confusion is accepted as an incidental or secondary component of another condition. A patient with injuries from a motor vehicle crash or with dyspnea may be confused, but the primary condition overshadows the underlying abnormal mental status. When confusion exists as an isolated or unexplained finding, it is more likely to receive full and immediate consideration by the clinician. Confusion is estimated to occur in 2% of emergency department (ED) patients, 10% of all hospitalized patients, and 50% of elderly hospitalized patients.

Pathophysiology

Conceptually, consciousness may be divided into elements of alertness or arousal and elements constituting content of consciousness. Confusion is largely a problem of the content portion of consciousness. Many different clinical processes may disrupt optimal cortical functioning and result in confusion. The pathophysiology is not straightforward. Widespread cortical dysfunction is thought to result from substrate deficit (hypoglycemia or hypoxemia), neurotransmitter dysfunction, or circulatory dysfunction. Compounding this problem is the idea that the reserve of central nervous system (CNS) function varies from individual to individual; individuals with a pre-existing impairment may become confused after even minor changes in their normal state.

Diagnostic Approach

Differential Considerations

The observation of acute confusion prompts a search for an underlying cause. Four groups of disorders encompass most causes of diffuse cortical dysfunction: (1) systemic diseases secondarily affecting the CNS, (2) primary intracranial disease, (3) exogenous toxins, and (4) drug withdrawal states (Box 13-1). Focal cortical dysfunction, such as from tumor or stroke, typically does not cause confusion, although exceptions are encountered. Likewise, subcortical or brainstem dysfunction most frequently results in a diminished level of alertness and consciousness, not confusion.

Rapid Assessment and Stabilization

Most patients with acute confusion do not require immediate interventions. Three crucial exceptions are hypoglycemia, hypoxia, and shock. A complete set of vital signs, including temperature and oxyhemoglobin saturation, and a bedside blood glucose level should be determined promptly for all confused patients. Oral or intravenous glucose therapy is indicated if low blood glucose is discovered. Supplemental oxygen and intravenous fluid are administered as necessary.

Patients should be protected from harming themselves or others. Close observation may need to be supplemented by medications or physical restraint. Family members may offer valuable assistance in observing and comforting the patient.

In a patient with abnormal or unstable vital signs, initial diagnostic and management efforts are directed toward treatment of the systemic condition. A confused patient with acute pulmonary edema, hypoxia, and confusion obviously requires evaluation and treatment of the pulmonary edema, not a screening test for cognitive functioning.
Generally, in patients with schizophrenia and other psychiatric disorders, tests of cognition, orientation, and attention are normal unless the condition is severe. The term *psychosis* implies a disorder of reality testing and thought organization severe enough to interfere with normal daily functioning. Psychosis is a nonspecific syndrome, and careful evaluation is required to differentiate between psychiatric and organic causes of confusion. A patient with an altered state of consciousness including confusion is evaluated by taking a focused history and conducting a pertinent examination, performing rapid bedside screening investigations, and observing the response to certain therapies (e.g., dextrose or naloxone). Additional evaluation may include laboratory testing and diagnostic imaging with various modalities. Useful information that provides the diagnosis or strongly suggests the etiology is found roughly in descending order from the patient’s history, the examination including results of rapid bedside testing, and the response to ED therapies; the results of laboratory testing and diagnostic imaging are less often useful.

**Pivotal Findings**

A patient with an altered state of consciousness including confusion is evaluated by taking a focused history and conducting a pertinent examination, performing rapid bedside screening investigations, and observing the response to certain therapies (e.g., dextrose or naloxone). Additional evaluation may include laboratory testing and diagnostic imaging with various modalities. Useful information that provides the diagnosis or strongly suggests the etiology is found roughly in descending order from the patient’s history, the examination including results of rapid bedside testing, and the response to ED therapies; the results of laboratory testing and diagnostic imaging are less often useful.

**History**

Confusion is often reported by family members or caregivers; frequently the patient is not aware of the confusion and seemingly glosses over problems. Families may articulate the complaint as confusion but also may describe rambling, disorientation, speaking to persons not there, the patient’s inability to find his or her way around familiar surroundings, or simply “not being right.” An essential goal of the history is to determine when the patient last exhibited “normal” thinking and behavior.

Attention deficit is the common denominator in confusional states. The initial task in evaluating the patient is to define the symptoms and severity of confusion. The specific behaviors that are of concern to the patient or caregivers should be defined. Often, the family is the most valuable source for information; a physician or other caregiver with an established relationship with the patient also may be helpful. The duration of the confusion, any recent changes in medications, and recent illnesses are important points in the clinical history. Hallucinations are not unique to psychiatric illness and can commonly occur in confusion states, especially delirium. Hallucinations in delirium tend to be visual (with or without auditory components), powerful, fleeting, and poorly organized. A history of medication or substance abuse and any recent changes, especially cessation of benzodiazepines or ethanol, should be sought.

**Physical Examination**

The patient’s confusion may be obvious at the bedside. In other cases, confusion may be subtle, and informal assessment of mental status and cognitive abilities may fail to detect it. The mini-mental state examination (MMSE) (Fig. 13-1) commonly is recommended as a screening instrument but is used infrequently in the ED because of the time required to administer it. A more rapidly performed screening tool, the Quick Confusion Scale (QCS; Fig. 13-2), has been developed and tested in ED patients. This tool objectively measures elements of the patient’s mental status in 2 to 3 minutes and correlates well with the MMSE. The tasks measured by either the MMSE or the QCS require adequate attention on
the part of the patient. If the patient’s attention span is greatly impaired, detailed testing may be impossible. Digit repetition forward (five or six digits) and backward (four digits) is a brief screen for attention function. Alternatively, spelling a commonly used word backward (“world” is frequently used) measures a patient’s ability to concentrate. Screening tests may detect confusion not obvious in casual conversation, identifying the need for further investigations.12,13

The physical examination may suggest a cause for confusion such as congestive heart failure or pneumonia. A fever suggests an infection as the cause of altered mental status and should prompt a search for the source, particularly urinary tract infection in the elder patient. Any new focal neurologic findings suggest a possible mass lesion or stroke and should trigger neuroimaging. In this regard, testing of gait and tandem gait, if possible, may be invaluable. Aphasia, fluent or nonfluent, is a focal sign suggesting a lesion in the dominant cerebral hemisphere. In confusional states, speech may be abnormal and is often incoherent, and the rate of speech may be either rapid or slowed. Involuntary movements, such as asterixis or tremor, may be present. The various toxidromes may assist in the identification of an intoxication or drug effect as the cause of confusion.

**Laboratory Tests**

The results of the history and physical examination frequently guide the clinician in the choice of laboratory tests most likely to yield valuable diagnostic information. Pulse oximetry may reveal hypoxia, or bedside glucose testing may reveal hypoglycemia or hyperglycemia. In the presence of a fever, chest radiography and urinalysis often reveal the source of the infection causing the altered mentation. In elder patients, urinalysis should be performed whether or not fever is present. Other tests commonly available in the ED and useful in the evaluation of a confused patient are serum electrolyte testing (especially sodium) and electrocardiography. Electrocardiography is indicated in elderly patients because myocardial infarction may present as confusion. The complete blood count, although commonly performed, is unlikely to provide useful diagnostic clues. Arterial blood gas testing is rarely indicated or useful, unless pulse oximetry is not reliable.

If common and simple tests do not suggest a solution, more complex testing should be initiated in the ED, observation unit, or inpatient service. The clinical situation and overall condition of the patient determine the speed and direction of evaluation. Additional laboratory work is often of decreasing yield but may reveal the cause of confusion. Serum ammonia, calcium, thyroid function, and selected drug and toxicologic testing may be ordered in this second tier of evaluation. Blood and urine cultures should be obtained in the febrile patient when hospital admission is anticipated and a clear infectious source is not evident. Paracentesis or thoracentesis may be appropriate if ascites or pleural effusion is present. Cranial computed tomography (CT) scanning is usually done to screen for CNS lesions in the absence of another identified source for the confusion. Focal findings on CT increase the yield of this test, but unanticipated abnormalities are often found on neuroimaging. Lumbar puncture may discover or exclude CNS infection if no other source has been identified. Cerebrospinal fluid examination may clarify a diagnosis of bacterial meningitis, encephalitis, aseptic meningitis, or subarachnoid hemorrhage. If the cause of confusion remains unclear or if the patient is unable to function safely in his or her current environment, admission may be necessary for additional ongoing assessment, including diagnostic testing not usually available in the ED, such as magnetic resonance imaging or electroencephalography.5
Certain critical and emergent diagnoses require prompt recognition to prevent morbidity or mortality (Box 13-3). The diagnosis of confusion implies the exclusion of other states of altered mental status, such as coma and decompensated psychiatric syndromes. A new focal neurologic deficit points to a focal defect of the CNS, which is less likely to cause the global cortical dysfunction necessary for confusion. Stroke rarely causes confusion, but resulting disturbances in speech or understanding may mimic a confusional state. The diagnosis of stroke is relatively straightforward if a new motor deficit is present. Occasionally, other focal neurologic abnormalities may mimic a confusional state. A person with a new visual field deficit and visual neglect may have difficulty ambulating in familiar surroundings and be labeled as confused, but this reflects focal neurologic injury and not a confusional state from global CNS dysfunction. Careful assessment of mental status assists in resolving the diagnostic dilemma. Frontal lobe dysfunction from stroke, subdural hematoma, or tumor may result in personality changes and the report of “confusion” by family or friends.

Altered mental status may be divided into three different categories depending on the findings of diminished level of consciousness, acute focal neurologic deficit, or abnormal attention span. Placement into one of these categories may guide the differential assessment and therapy (Fig. 13-3).

---

**DIFFERENTIAL DIAGNOSIS**

Certain critical and emergent diagnoses require prompt recognition to prevent morbidity or mortality (Box 13-3). The diagnosis of confusion implies the exclusion of other states of altered mental status, such as coma and decompensated psychiatric syndromes. A new focal neurologic deficit points to a focal defect of the CNS, which is less likely to cause the global cortical dysfunction necessary for confusion. Stroke rarely causes confusion, but resulting disturbances in speech or understanding may mimic a confusional state. The diagnosis of stroke is relatively straightforward if a new motor deficit is present. Occasionally, other focal neurologic abnormalities may mimic a confusional state. A person with a new visual field deficit and visual neglect may have difficulty ambulating in familiar surroundings and be labeled as confused, but this reflects focal neurologic injury and not a confusional state from global CNS dysfunction. Careful assessment of mental status assists in resolving the diagnostic dilemma. Frontal lobe dysfunction from stroke, subdural hematoma, or tumor may result in personality changes and the report of “confusion” by family or friends.

Altered mental status may be divided into three different categories depending on the findings of diminished level of consciousness, acute focal neurologic deficit, or abnormal attention span. Placement into one of these categories may guide the differential assessment and therapy (Fig. 13-3).

---

**EMPIRICAL MANAGEMENT**

Ideally, treatment is directed at the underlying cause of the confusion. Investigations continue until a likely diagnosis is discovered or consultation and admission are deemed necessary (Fig. 13-4). Many febrile patients are found to have a systemic infectious cause of the confusion. Urinary tract infections and pneumonia are the more common sources, but soft tissue infections also warrant consideration. CNS infections are encountered less frequently but have potentially devastating consequences if not recognized promptly. Antibiotic treatment for coverage of common causes of meningitis may be considered in ill febrile patients while definitive evaluation is in progress.

Postictal confusion is common in patients with seizures but should improve within 20 to 30 minutes. If the patient remains unconscious or confused after a seizure, the possibility of ongoing or intermittent seizure activity (i.e., nonconvulsive seizures) should be considered. Nonconvulsive status epilepticus, an epileptic twilight state, is unusual but does occur, and may be particularly difficult to recognize in the elderly (see also Chapter 15).

Sometimes it may be necessary to treat confusion or agitation for patient safety. Environmental manipulations, such as dim lighting or psychosocial support, may be helpful. Confinement or physical restraint may be necessary at times for patient safety; institutional guidelines should be followed. Benzodiazepines or butyrophenones may be used if necessary to decrease agitation. These medications may alter mental status further, making evaluation more difficult.
Most patients presenting with confusion are admitted to the hospital or ED observation unit for additional diagnostic procedures, extended observation, and treatment. Exceptions include patients with rapidly resolved confusional states after treatment for insulin-induced hypoglycemia, after generalized seizures of known origin, or after recovering from self-limiting intoxicants or withdrawal states, such as those related to ethanol or recreational drugs. These patients may be observed and then discharged after successful identification and resolution of acute confusional state. Unresolved confusion or unexplained findings on repeat mental status screen should prompt admission or careful reevaluation before considering discharge.

CHAPTER 14  Depressed Consciousness and Coma

Jeremy L. Cooke

PERSPECTIVE

Epidemiology

Depressed consciousness is a common presenting complaint in the emergency department (ED). It represents a spectrum of disease that ranges from sleepiness or decreased alertness to frank coma. The majority of cases of depressed consciousness and coma are caused by metabolic or systemic derangements, and the remainder are caused by structural lesions.¹ The differential diagnosis for depressed level of consciousness often overlaps that for confusion (see Chapter 13).

Pathophysiology

Consciousness includes the properties of arousal, which is defined as the awareness of one’s self or surroundings, and cognition. Cognition is the combination of orientation, the accurate perception of what is experienced, judgment, the ability to process input data to generate more meaningful information, and memory, the ability to store and retrieve information. The ascending reticular activating system (ARAS) is the neuroanatomic structure primarily responsible for arousal. It is located in the paramedian tegmental zone in the dorsal part of the brainstem (Fig. 14-1). The input of somatic and sensory stimuli to the cerebral cortex is controlled by the ARAS and functions to initiate arousal from sleep. The brain’s cognition centers are located primarily in the cerebral cortex.

Insults to the cerebral cortex or brainstem can each independently cause depressed consciousness or coma. These structures are vulnerable to metabolic derangements, toxins, or mechanical injury. Typically, both cerebral hemispheres need to be affected to induce coma and this also depends on the size and speed of progression of the insult. Localized, unilateral lesions in the cerebral cortex usually do not induce depressed consciousness or coma even if other cognitive functions are impaired. In contrast, a completely intact brainstem is necessary for arousal. Small focal lesions in the brainstem can affect the ARAS. If the ARAS is impaired, the cerebral cortex cannot be aroused and depressed consciousness or coma occurs.

Potential causes of depressed consciousness can be broken down into a few general categories. Metabolic or systemic causes of coma can include hypoxia, hypoperfusion, infection, toxic drug effects, or electrolyte disturbances. Hypoxia can be the result of congestive heart failure (CHF), pulmonary embolism, carbon monoxide poisoning, or severe pulmonary com-
Clinical Evaluation

The clinical evaluation and stabilization of patients with depressed consciousness occur simultaneously with the diagnosis in the ED. The differential diagnosis of depression of consciousness is extensive but can be greatly simplified by focusing attention on the distinguishing characteristics of the available patient history and physical examination (Boxes 14-1 and 14-2). Approaching the patient’s presentation systematically, beginning with a broad differential diagnosis, usually allows development of a short list of likely diagnoses early in the encounter.

History

Chief complaints relating to depressed consciousness vary widely. Family members may report the patient as being more difficult to arouse from sleep or less interactive. Often, family members or friends have alerted emergency medical services after the patient is “found down” and unarousable even with vigorous stimulation.

Family members, caregivers, or friends often can provide information that is unobtainable or unreliable from the patient who presents with depressed consciousness. They usually have some knowledge regarding the patient’s past medical history, which may include diabetes, liver or renal disease, vascular disease such as hypertension, stroke or transient ischaemic attacks, malignancy, seizures, immunocompromised states such as HIV, sickle cell disease or a history of organ transplant, or psychiatric illness. Symptoms in the hours to days preceding the occurrence of depressed consciousness are important. Specifically, the patient may have complained of headache, focal weakness or numbness, incoordination, or vision disturbances. The patient may have experienced nausea, vomiting, or fever. There may be a history of a traumatic fall or exposure to drugs or toxins. Family members may also be able to relay additional diagnostic clues such as rate of onset or waxing-waning characteristics of the patient’s symptoms.

Causes of depression of consciousness vary with patient age (Box 14-3). The elderly are particularly vulnerable to infec-
Hypoxia
Severe pulmonary disease (hypoventilation)
Severe anemia
Environmental/toxin
Methemoglobinemia
Cyanide
Carbon monoxide
Decreased atmospheric oxygen (high altitude)
Near-drowning

Disorders of Glucose
Hypoglycemia
Chronic alcohol abuse and liver disease
Excessive use of insulin or other hypoglycemic agents
Insulinoma
Hyperglycemia
Diabetic ketoacidosis
Nonketotic hyperosmolar coma

Decreased Cerebral Blood Flow
Hypovolemic shock
Cardiac
Vasovagal syncope
Arrhythmias
Myocardial infarction
Valvular disorders
Congestive heart failure
Pericardial effusion/tamponade
Myocarditis
Infectious
Septic shock
Bacterial meningitis
Vascular/hematologic
Hypertensive encephalopathy
Pseudotumor cerebri
Hyperviscosity (sickle cell, polycythemia)
Hyperventilation
Cerebral lupus vasculitis
Thrombotic thrombocytopenic purpura
Disseminated intravascular coagulation

Metabolic Cofactor Deficiency
Thiamine (Wernicke-Korsakoff syndrome)
Pyridoxine (isoniazid overdose)
Folic acid (chronic alcohol abuse)
Cyanocobalamin
Niacin

Electrolyte/pH Disturbances
Acidosis/alkalosis
Hypernatremia/hyponatremia*
Hypercalcemia/hypocalcemia
Hyperphosphatemia
Hypermagnesemia/hypomagnesemia

Endocrine Disorders
Myxedema coma, thyrotoxicosis
Hypopituitarism
Addison’s disease (primary or secondary)
Cushing’s disease
Pheochromocytoma
Hyperparathyroidism/hypoparathyroidism

Endogenous Toxins
Hyperammonemia (liver failure)
Uremia (renal disease)
Carbon dioxide narcosis (pulmonary disease)
Porphyria

Exogenous Toxins
Alcohols
Ethanol, isopropyl alcohol, methanol, ethylene glycol
Acid poisons
Salicylates
Paraldehyde
Ammonium chloride
Antidepressant medications
Lithium
Tricyclic antidepressants (TCAs)
Selective serotonin reuptake inhibitors (SSRIs)
Monamine oxidase inhibitors (MAOIs)

Stimulants
Amphetamines/methamphetamine
Cocaine
Over-the-counter sympathomimetics
Narcotics/opiates
Morphine
Heroin
Codeine, oxycodone, meperidine, hydrocodone
Methadone
Fentanyl
Propoxyphene
Sedative-hypnotics
Benzodiazepines
Barbiturates
Rohypnol
Bromide

Hallucinogens
Lysergic acid diethylamide (LSD)
Marijuana
Mescaline, peyote
Mushrooms
Phencyclidine (PCP)
Herbs/plants
Aconite
Jimson weed
Morning glory
Volatile substances
Hydrocarbons (gasoline, butane, toluene, benzene, chloroform)
Nitrites
Anesthetic agents (nitrous oxide, ether)

Other
γ-Hydroxybutyrate (GHB)
Ketamine
Penicillin
Cardiac glycosides
Anticonvulsants
Steroids
Heavy metals
Cimetidine
Organophosphates

Disorders of Temperature
Regulation/Environmental
Hypothermia
Heat stroke
Malignant hyperthermia
Neuroleptic malignant syndrome
High-altitude cerebral edema (HACE)
Dysbarism

Primary Glial or Neuronal Disorders
Adrenoleukodystrophy
Creutzfeldt-Jakob disease
Progressive multifocal leukoencephalopathy
Marchiafava-Bignami disease
Gliomatosis cerebri
Central pontine myelinolysis

Other Disorders of Unknown Etiology
Seizures
Postictal states
Reye’s syndrome†
Intussusception†

*Can be associated with dilution of formula in infant feeding.
†Prominent in the pediatric population.

Physical Examination
The severity of presenting symptoms dictates the speed needed for stabilization and diagnosis. After necessary stabilization measures have been instituted (e.g., intubation of the frankly comatose patient), a systematic examination is conducted. Level of consciousness is determined by the patient’s ability to speak in full, coherent sentences and to respond...
appropriately to the examiner. A rapid, directed neurologic screening examination can determine whether the patient has a significant focal motor deficit. The presence of a distinctive odor on the breath, although uncommon, can cue the examiner to the presence of alcohol, ketones (diabetic/alcoholic ketoacidosis), or bitter almonds (cyanide toxicity). Undressing the patient promptly and completely permits evaluation for signs of trauma or skin lesions suggesting overwhelming infection.

Vital signs are paramount in the initial assessment of all patients. Significant hypotension with depressed consciousness suggests shock, and both causes and therapy should be addressed immediately. Late-stage, severe elevation in intracranial pressure (ICP) can cause bradycardia and hypertension. Tachycardia and hypotension can be the result of primary cardiac, infectious, or toxic/metabolic causes. Both hypothermia and hyperthermia can result in altered mental status whether from infectious, structural, or toxic/metabolic causes. Hyperventilation, Kussmaul’s or Cheyne-Stokes breathing, agonal breathing, apnea, or other alterations in respiratory patterns can suggest primary CNS abnormalities or toxic/metabolic derangements.

Immediately after an assessment of the patient’s vital signs, a head-to-toe physical examination is performed. A methodical and complete head and neck examination is conducted, with particular emphasis on examination of the papillary reflexes and eye movements (see later discussion) and any indications of head trauma (hemotympanum, scalp hematoma). The mucous membranes may suggest specific toxidromes.

Examination of the neck should focus on evidence of infection, including nuchal rigidity, lymphadenopathy, or fluctuance. The cervical spine should be immobilized if there are signs of neck trauma, such as cervical spine tenderness, or evidence of blunt external trauma. Stridor indicates respiratory distress typically from infection, edema, or foreign body aspiration.

Chest examination focuses on pulmonary function, infection, cardiac output, and the presence of injury. Potentially helpful abdominal findings include ascites, hepatosplenomegaly, ecchymosis, or striae. Gross blood, purulent drainage, or retained foreign bodies should be sought on genitourinary and rectal examination. In the absence or presence of signs of trauma, lesions on the skin such as rashes, signs of drug use (needle “tracks” or medication patches), or embolic phenomena can be differential clues.

A systematic neurologic examination, with particular attention paid to the eyes, is the most useful tool in differentiating a structural from a systemic or metabolic etiology of depressed consciousness or coma. A head-to-toe approach is a proven strategy. This should include evaluation of the patient’s Glasgow Coma Scale (GCS) (Box 14-4), level of alertness, cranial nerves, strength, reflexes, and cerebellar functions with emphasis on gait, pronator drift, finger-to-nose, heel-to-shin, rapid alternating movements, and Romberg testing. A change of two or more points in serial GCS testing represents a significant change in the patient’s level of consciousness.

Discovery of a focal neurologic deficit is suggestive of a structural etiology. Particular attention should be paid to a focused eye examination during which a helpful amount of information can be obtained. Unilateral dilatation of a pupil (“blown pupil”) and loss of reactivity in a comatose patient are ominous signs of uncal herniation requiring immediate neurosurgical consultation and intervention. Papilledema in the setting of increased ICP or retinal hemorrhage associated with trauma can be found on funduscopic examination. The eye examination should also include testing of eye movements, which are coordinated by the medial longitudinal fasciculus located in the brainstem and ocular centers located in the cerebral cortex. Cranial nerves III, IV, and VI are responsible for control of the extraocular muscles. Cranial nerve III paralysis results in a persistently abducted eye, whereas a persistently adducted eye is caused by paralysis of cranial nerve VI. In the setting of trauma, a unilateral third cranial nerve palsy suggests an ipsilateral compressive lesion such as seen with epidural hematoma. Cranial nerve VI palsies are often nonlocalizing as the nerve has a long intracranial course and compressive forces from intracranial mass effects (tumor, traumatic hematoma, increased ICP, etc.) may compromise cranial nerve function anywhere in its course. Horizontal disconjugate gaze is an important finding and is commonly seen in patients who are sedated, drowsy, or intoxicated. Disconjugate gaze found...
in the vertical plane is usually more serious and suggests cerebellar or pontine dysfunction.

Oculocephalic (doll’s eyes) and oculovestibular reflex testing are useful in looking at the functional integrity of the brainstem. These tests, if negative, make structural lesions in the brainstem very unlikely as the source of the patient’s altered mental status.

If there are no contraindications, such as suspected cervical spine injury, oculocephalic testing is accomplished by observing the patient’s eye movements while the head is turned from side to side. Patients who exhibit a maintained forward gaze despite head turning (“doll’s eyes reflex”) are unlikely to have a brainstem-mediated cause of coma. If the eyes remain in a fixed position within the orbits, turning in unison with the head, brainstem dysfunction is suggested. Oculovestibular or “cold water caloric” testing is a more sensitive test for brainstem involvement and cannot voluntarily be resisted (Fig. 14-2). After elevation of the patient’s head to 30° (this can be done in patients whose cervical spine is not cleared by placing the bed in the reverse Trendelenburg position), 10 to 30 mL of ice water is used to irrigate the external auditory canal. Tympanic membrane perforation and cerumen impaction should be ruled out prior to performing this test. In patients who have an intact brainstem, the response is a slow conjugate deviation of gaze toward the side of the cold water stimulus lasting 30 to 120 seconds. The reflex is short-lived and followed by corrective fast beats of nystagmus toward the midline. This corrective nystagmus is described by the mnemonic COWS, which stands for “cold-opposite, warm-same.” If there is no response to the irrigation, brainstem dysfunction is possible.

**Figure 14-2.** Oculocephalogyric (caloric) responses to various central nervous system pathologic conditions. MLF, medial longitudinal fasciculus.

### Diagnostic Algorithm

Information gathered from the history and physical examination of the patient with depressed consciousness must be used to direct the approach to diagnostic testing (Fig. 14-3). Most often, this information points toward a systemic or metabolic rather than a structural etiology. Neuroimaging studies are performed early in patients with suggested structural causes, but should not precede treatment of quickly reversible conditions such as possible opioid overdose or hypoglycemia.

Systemic or metabolic causes of depressed consciousness and coma are most often found on analysis of laboratory studies. Bedside glucose testing definitively confirms or excludes hypoglycemia. Serum electrolytes identify derangements in sodium, CO₂, or the anion gap. Changes in serum calcium can be a marker for metastatic disease. A urine dip test is a quick way to identify infection, ketones, or spilling of glucose. Urinalysis itself provides valuable information regarding volume status (specific gravity), infection, and the possible presence of calcium oxalate crystals in the setting of ethylene glycol ingestion. Urine drug testing may be helpful if another cause is not forthcoming.

Although an elevated white blood cell count can be a marker for infection, it is nonspecific and rarely helpful. An abnormally low white blood cell count, however, suggests an immunocompromised state and should urgently direct clinical investigation toward an infectious etiology. Thrombocytopenia can be a marker for sepsis or intracranial hemorrhage and may sound a cautionary note against an invasive procedure such as obtaining central venous access or performing a lumbar puncture. Elevated results from serum coagulation studies can be a marker for bleeding tendencies or liver disease. Serum ammonia levels are controversial and have not been shown to be a reliable marker in the setting of depressed consciousness. Thyroid function studies can reveal myxedema coma from hypothyroidism. When CNS pathology such as infection or hemorrhage is suggested but not seen on neuroimaging studies, cerebrospinal fluid analysis is undertaken.

Noncontrast computed tomography (CT) of the brain is the preliminary imaging modality of choice in the setting of depressed consciousness and coma. In the majority of ED settings, it is quickly available, making it more suitable for the patient with borderline stability. It is sufficiently sensitive to detect most intracranial hemorrhages that are large enough to cause coma. Contrast-enhanced CT may be used if a tumor or infection is possible. Linear artifacts created by the thick skull base can limit the view of the posterior fossa on CT. For this reason, magnetic resonance imaging of the brain is generally more useful for identifying structural lesions in this region; however, this modality is less feasible in most ED settings due to its cost and limited availability. Angiography may be available in larger tertiary care centers for use in the diagnosis or treatment of intracerebral aneurysms or arteriovenous malformations after initial identification of an intracranial hemorrhage on noncontrast CT.

Plain radiography may identify severe pneumonia or acute respiratory distress syndrome, or it may rarely reveal specific types of heavy-metal ingestions such as mercury, iron, or lead in the pediatric population. Electrocardiograms can point to certain ingestions (tricyclic antidepressants, etc.), electrolyte abnormalities (potassium, calcium, etc.), or hypothermia. If nonconvulsive status epilepticus is suggested, or if a patient with status epilepticus has required neuromuscular blockade,
continuous electroencephalographic monitoring, if available, can provide key information about the patient’s status and guide therapy.

**Empirical Management**

Initial establishment of airway, breathing, and circulation (ABCs) is of primary importance in stabilizing the patient with altered mental status. Initiation of IV access combined with the administration of oxygen and continuous telemetry monitoring should happen concomitantly within the first few minutes of the patient’s arrival. In patients with a GCS score lower than 8, definitive airway control should be obtained unless the coma is readily reversible (e.g., hypoglycemia, opioid overdose). Patients with possible increased ICP should receive lidocaine prior to rapid sequence intubation (see
Trauma patients require spinal immobilization in addition to indicated fluid resuscitation. Reversible causes of the patient's condition should be sought concomitantly with initial stabilization. Administration of the components of the “GI cocktail,” which include dextrose, naloxone, and thiamine, can quickly reverse the alterations in mental status caused by hypoglycemia, narcotic overdose, and thiamine deficiency, respectively. Further therapy and workup will be dictated by the patient’s history and physical examination. Specific attention should be given to identifying the focal neurologic abnormalities, including pupillary reflexes and pathologic eye movements that suggest mass effect or depressed brainstem function, prompting neuroimaging and evaluation by a neurosurgeon. Empirical administration of mannitol is indicated when there is evidence of transtentorial herniation in this setting. Ventriculostomy and ICP monitoring are commonly performed by the neurosurgeon in the ED. In trauma patients with suspected epidural hematoma who have evidence of brain herniation, the use of burr holes in the skull on the side of the dilated pupil may be a last resort. In patients with compromised brainstem function who lack evidence of herniation, a workup to investigate possible exposure to toxins or metabolic imbalances should proceed while supportive care is provided. Brain tissue is considered to be unsalvageable in patients who have not received sedative medications, are normothermic, and demonstrate lack of brainstem reflex activity.

In patients who demonstrate normal brainstem function, the workup proceeds as supportive care is provided. When an infectious cause is suggested, empirical administration of a broad-spectrum antibiotic should not be delayed for lumbar puncture or other diagnostic tools. Lesions or masses found on brain imaging should prompt evaluation by a neurosurgeon and, if indicated, early operative intervention. In patients in whom a toxic ingestion is possible, activated charcoal is of no proven benefit in most cases and gastric emptying is rarely indicated (see Chapter 145). Specific toxin antidotes, if indicated, can be given, with consultation with a local or regional poison center when required. Early hemodialysis after consultation with a nephrologist should also be considered in patients who have toxic or metabolic abnormalities amenable to this therapy.

The vast majority of patients who present with depressed consciousness or coma require admission to the hospital for further treatment and workup. Some patients who have returned to their baseline mental status after reversal of hypoglycemia or opioid overdose may be suitable for discharge directly from the ED or ED observation unit after a period of observation. Patients with alcohol or recreational drug intoxication and no other discernible cause of altered mental status can be discharged when they are clinically sober.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Seizures

Epilepsy is defined as recurrent unprovoked seizures due to a genetically determined or acquired brain disorder; it is not an appropriate term for seizures that occur intermittently and predictably after a known insult, such as alcohol intoxication and withdrawal.

Presentation to the emergency department (ED) with a generalized convulsive seizure prompts immediate concern for airway protection and stabilization, followed by a focused search for the cause. Nonconvulsive seizures, which are much less common, may be relatively obscure in their presentation, more diverse in their etiology, and are sometimes more difficult to recognize and control acutely.

Epidemiology and Classification

It is estimated that 6% of the U.S. population experience at least one nonfebrile seizure during their lifetime; the annual incidence among adults is 84 per 100,000 population, and more than half of these individuals develop epilepsy. In one study, approximately 1% of ED visits were for seizure-related complaints. Nearly half of these patients had alcohol or low antiepileptic drug levels implicated as contributing factors.

Seizures can be classified as primary or secondary (the latter also termed reactive), as generalized or focal (partial), or as convulsive or nonconvulsive. Table 15-1 shows the distribution of seizures in a typical population of patients. A generalized seizure is defined as abnormal neuronal activity in both cerebral hemispheres. Seizures may be divided into tonic-clonic, absence, and myoclonic. Partial seizures or focal seizures usually involve one hemisphere. They are divided into simple partial (in which consciousness is maintained), complex partial (in which consciousness is lost), and those that become secondarily generalized. Some seizures are impossible to classify because of inadequate or inaccurate description of the ictal activity.

Status epilepticus is defined as at least 30 minutes of persistent seizures or a series of recurrent seizures without intervening return to full consciousness, although several authors have proposed shortening the time criterion from 30 minutes to 5 minutes.

Secondary seizures may occur as a result of a vast array of injuries and of illnesses such as intoxication or poisoning, encephalitis, encephalopathy, organ failure, other metabolic disturbances, infections of the central nervous system, cerebral tumors, pregnancy, and, paradoxically, supratherapeutic levels of anticonvulsants.

Seizures in children follow a different distribution, primarily because of the relatively high incidence of febrile seizures and the frequently uncertain observational history of possible ictal activity. Febrile seizure is the most common pediatric seizure, occurring in 2 to 5% of children between 6 months and 5 years of age; 20 to 30% of those children have at least one recurrence. It is important to differentiate between febrile seizure and seizure with fever. First-time seizures in infants younger than 6 months may indicate significant underlying pathology and warrant a full assessment.

Pathophysiology

Seizures occur when abnormal increased electrical activity of the initiating neurons activates adjacent neurons and propagates until the thalamus and other subcortical structures are similarly stimulated. At a cellular level, the pathophysiology is not well understood, although recent research in specific epilepsy syndromes is elucidating possible mechanisms. Investigation of rare inherited epilepsy syndromes has identified mutations in neuronal ion channel proteins, limiting intracellular passage of potassium. Given that the potassium current is the primary force behind repolarization of membranes, depolarization is prolonged in these patients, leading to an increase in neuronal hyperexcitability. Other studies have found that malformations of cortical development and glial cells may play a role in epileptogenesis.

Clinical seizure activity typically, but not always, reflects the initiating focus. When the ictal discharge extends below the cortex to deeper structures, the reticular activating system in the brainstem may be affected, altering consciousness. In generalized seizures, the focus is often deep and midline, which explains the prompt loss of consciousness and bilateral involvement. Seizures are typically self-limited; at some point the hyperpolarization subsides and the bursts of electrical discharges from the focus terminate. This cessation may be related to reflex inhibition, neuronal exhaustion, or alteration of the local balance of neurotransmitters.

Partial seizures may represent a similar pathophysiologic process in which less recruitment occurs and the ictal activity does not cross the midline. Because of the more limited focus of abnormal activity, convulsive motor activity may not be the predominant clinical manifestation.
DIAGNOSTIC APPROACH

Differential Considerations

Because an incorrect diagnosis is expensive and involves loss of driving privileges and exposure to potentially toxic medicines, the first diagnostic task is to determine whether the patient is having a “true” seizure. Ictal activity can be irrefutably verified only by electroencephalography (EEG). Other abnormal movements and states of consciousness, including pseudoseizures, can be confused with ictal activity. Other disorders mimicking seizures are listed in Table 15-2.

Syncope, whether vasodepressive (vagal syncope), orthostatic, or dysrhythmia related, can be confused with seizures by observers. A sudden loss of consciousness followed by abnormal movements can be ictal or syncopal in origin, hence the consideration “fit versus faint.” One video analysis of 56 brief syncopal episodes showed myoclonic activity in 90% of patients, together with frequent head turns, upward gaze, oral automatisms, and righting movements. These are likely a transient response by the brain to sudden deprivation of blood flow. Generally, ictal tonic-clonic movements are more forceful and prolonged than the “twitches” sometimes associated with fainting. In addition, most generalized seizures are characterized by a postictal state (an important exception being atomic drop attack ictus), which syncope patients do not manifest.

The cause of an unwitnessed, unprovoked loss of consciousness with a fall, after which the patient presents to the ED, may be difficult to determine. Suggestions of an ictal diagnosis include retrograde amnesia, loss of continence, and evidence of tongue biting. If blood was drawn by emergency medical service personnel soon after a true seizure, it often demonstrates a metabolic acidosis that has resolved by the time a repeat analysis is performed in the ED.

Rapid Assessment and Stabilization

The patient who arrives with a history of possible seizure activity should be placed in a monitored area of the ED and prepared for prompt physician examination. An IV line or saline lock catheter should be placed in case anticonvulsants are emergently indicated. Blood glucose is checked at the bedside, and a thorough list of all medications currently being used by the patient is obtained.

If the patient is seizing in the ED, the first step is to confirm that a pulse is present and that the “seizure” activity is not the result of cerebral hypoxia from lack of blood flow. After this, attention is paid to protecting and maintaining the airway, including use of a nasopharyngeal airway and ready availability of oxygen and suction. The patient should be protected from self-injury during this time.

*Electroencephalography provides the definitive diagnosis in unclear cases. CNS, central nervous system.
A pulse oximeter should be applied and oxygen administered as necessary. Optimally, the patient is turned on his or her side to protect the airway from aspiration. If the patient is immobilized on a spine board after trauma, the entire board is tipped up to one side. Preparation should be made for endotracheal intubation in case anticonvulsant drugs fail to terminate the seizure. While these procedures are accomplished, an assistant should be establishing IV access.11

Hypoglycemia is the most common metabolic cause of seizure activity. The only treatment required for the patient may be administration of IV glucose. Prolonged seizure activity may also cause hypoglycemia, so that the cause-and-effect relationship may sometimes be reversed and further therapy is required. Benzodiazepines are the optimal first-line agents for stopping seizure activity in patients of all ages. Available agents include lorazepam (Ativan), diazepam (Valium), and midazolam (Versed). All three are efficacious in terminating seizure activity (see Table 15-3 for doses), but if IV access cannot be achieved, diazepam may be given rectally, endotracheally, or intraosseously; rectal diazepam stops seizures in 70% of patients, compared with 60 to 80% for IV dosing.12 Midazolam can be given intramuscularly, and recent research shows that buccal midazolam works in children.13 If IV access is obtained, however, lorazepam is the agent of choice for initial management of status epilepticus, particularly because its longer half-life leads to less recurrence of seizures.14 Lorazepam is also specifically recommended for alcohol withdrawal seizures, again due to its longer duration of action.15

If benzodiazepines do not abort seizure activity, the airway should be reevaluated. If the patient’s ability to protect the airway is compromised or oxygen saturation remains persistently below 90%, emergent intubation should be performed. If the seizure has not terminated 5 to 7 minutes after benzodiazepine administration, or if the maximum dose of lorazepam (0.1 mg/kg) or diazepam (0.15 mg/kg)16 has been reached, a second drug should be given.16 Use of maximal doses of benzodiazepines may require intubation and ventilatory support. Phenytoin is recommended as second-line therapy for adults with persistent seizure activity.16 The prodrug, fosphenytoin, can be administered more quickly, can be given intramuscularly, and has less tendency to cause hypotension, but is significantly more expensive.17 (See Table 15-3).18,19 Second-line therapy for children is phenobarbital. Third-line therapy is phenytoin for children and phenobarbital for adults.20,21 IV valproic acid is safe24 and should be considered for patients who are on chronic valproic therapy and whose levels are subtherapeutic.25 If a patient’s seizures are refractory to benzodiazepines, consider isoniazid overdose as the cause. Pyridoxine

is the only fully effective pharmacologic treatment for toxic isoniazid seizures, although benzodiazepines have been shown to suppress seizure activity in some cases. In seizing females of childbearing age, eclampsia should be considered; in this case, intravenous magnesium (6 g) is the drug of choice. (See Chapter 177.) Approximately 10% of patients will have a second seizure despite magnesium; these patients should get a second 2-g bolus of magnesium. If the eclamptic patient continues seizing, magnesium dosing should be repeated; refractory eclamptic seizures can also respond to benzodiazepines or barbiturates with or without phenytoin. Children and psychiatric patients at risk for water intoxication should be considered potential candidates for hypertonic saline therapy, after laboratory confirmation of hyponatremia.

Patients who remain unresponsive to the third-level choice of pharmacologic intervention are by definition in refractory status epilepticus. Further choices for therapy at that juncture are general anesthetic doses of midazolam or propofol, barbiturates or isoflurane anesthesia; all of which mandate endotracheal intubation. A neuromuscular blocking agent is administered concomitantly to reduce the metabolic burden and potential hyperthermia that can ensue from prolonged status seizures. Anesthetic dosing of midazolam is 0.2 to 0.3 mg/kg bolus, then 0.05 to 2.0 mg/kg/hr, and for propofol it is 2 to 4 mg/kg, then 1 to 15 mg/kg/hr. Both drugs are usually well-tolerated and can be titrated to effect, although propofol is preferable because of its rapid onset and offset of action, which allows the patient to be “awakened” intermittently for examination in the event that continuous EEG monitoring is not available.

Pivotal Findings

When the patient is stabilized with a secure airway and ictal activity is controlled, attention is turned to gathering more complete data.

History

History taking in the patient with seizure is directed by two main questions. First, “Was the incident truly a seizure?” This is important because of the broad differential diagnosis for seizures (see Table 15-2) and the notoriously inaccurate history should focus on intercurrent illness or trauma, drug or alcohol use, potential adverse drug-drug interactions with anticonvulsants, medication compliance, a recent change in anticonvulsant dosing regimens, or a change in ictal pattern or characteristics.

Supratherapeutic and toxic levels of some anticonvulsants such as phenytoin and carbamazepine, whether attained chronically or after acute overdose, may cause seizures. If empiric anticonvulsant therapy is indicated before the serum level is available, only 50% of a full loading dose should be given unless the patient is known reliably not to be taking anticonvulsant medication.

If the patient does not have a history of seizures and the description of the event is truly consistent with a seizure, the history should focus on potential underlying medical, toxicologic, or neurologic causes.

A personal history from the patient, close friend, relative, or medical record may reveal potential ictogenic factors such as recent or remote head trauma, developmental abnormalities, metabolic diseases, drug or alcohol abuse, sleep deprivation, pregnancy, recent travel, previous seizures, or use of herbal supplements. When no witness or family member is available, extensive questioning must await clearance of the postictal confusional state.

Physical Examination

The physical manifestations of convulsive ictal activity include hypertension, tachycardia, and tachypnea from sympathetic stimulation. These signs typically resolve quickly after the seizure activity ceases. With more prolonged convulsions, skeletal muscle damage, lactic acidosis, and, rarely, frank rhabdomyolysis may ensue. Autonomic discharges and bulbar muscle involvement may result in urinary or fecal incontinence, vomiting (with significant aspiration risk), tongue biting, and airway impairment. All of these signs are helpful discriminators in the differential evaluation of seizure-like spells.

After the seizure activity has ceased, resting vital signs should be evaluated. Fever and underlying infection can cause seizures, although there may be a low-grade temperature elevation immediately after a convulsive generalized seizure. Tachypnea, tachycardia, or an abnormal blood pressure that persists beyond the immediate postictal period may indicate toxic exposure, hypoxia, or a central nervous system lesion. Pertinent physical findings may include nuchal rigidity, stigmata of substance abuse, lymphadenopathy suggestive of HIV disease or malignancy, dysmorphic features, or skin lesions. The examination should also focus on potential adverse sequelae of convulsive seizures, such as head trauma, tongue injury, posterior shoulder dislocation, or back pain.

Finally, a complete neurologic examination must be performed. A persistent focal deficit after a seizure (e.g., Todd’s paralysis) often indicates the focal origin of the event but also can be evidence of an underlying stroke. The patient should be carefully examined for papilledema; elevated intracranial pressure can both cause and result from ictal activity. Failure to note steady improvement of postictal depression of consciousness suggests the possibility of an underlying encephalopathy or nonconvulsive status epilepticus.

Ancillary Testing

Laboratory. Routine screening studies such as a complete blood count and chemistry profile have little use in the neurologically normal, otherwise healthy, postictal patient with a known seizure disorder for whom a reliable history can be obtained.
Bedside blood glucose is measured early. Anticonvulsant levels are appropriate in patients known or thought to be taking anticonvulsant medication. Febrile patients are evaluated for the source of the fever. For medically ill adults (e.g., diabetic patients, cancer patients, patients with liver disease, patients taking medications that can affect serum electrolyte levels) and in those presenting with a first-time seizure, appropriate chemistry studies are ordered, including electrolytes and liver function tests. Directed toxicologic screens should be obtained if substance abuse is possible. Serum sodium should be evaluated, particularly if mental status remains altered after apparent recovery from the postictal state. Pregnancy testing is useful if eclampsia is possible. If there is any suggestion of meningitis or subarachnoid hemorrhage, lumbar puncture should be performed, with a preceding cranial computed tomography (CT) scan. Imaging. In the fully recovered patient without headache and with fully normal mental status and neurologic examination who has had a single, brief seizure, a cranial CT scan can be obtained in the ED or at a follow-up visit at the discretion of the treating physician. Table 15-4 lists the circumstances under which a head CT is recommended in the ED due to a higher likelihood of discovering an acute abnormality. The literature on this issue for first-time nonfebrile seizures in children is also inconclusive. Cranial CT is indicated in any age group when there is a possibility of head trauma, elevated intracranial pressure, intracranial mass, persistently abnormal mental status or focal neurologic abnormality, or HIV disease. Electroencephalography. EEG is not consistently available in the ED. It may be particularly useful in specific cases, such as the diagnosis of nonconvulsive status epilepticus, to monitor seizure activity after intubation and neuromuscular blockade, and to help differentiate seizures from other similar presentations. In general, EEGs are most appropriate for the follow-up evaluation of first-time seizures without clear cause after a complete ED evaluation.

**MANAGEMENT**

Usually, an acute seizure self-terminates or can be pharmacologically terminated before a need arises for active airway management. Rapidly reversible ictal insults (e.g., hypoglycemia, hypoxemia, isoniazid ingestion) should be considered and, if found, treated. Primary abortive therapy in the ED is accomplished as described earlier. Although a number of newer antiepileptic medications have become available, their therapeutic purpose is directed toward chronic rather than acute seizures.

Identifying a new-onset seizure in the ED generates consideration for further management. The choice to initiate anticonvulsant therapy depends on the risk of seizure recurrence and any underlying predisposing disease, and the risk of initiating anticonvulsant therapy is typically not made by the emergency physician. The initiation of anticonvulsant therapy after a single seizure is an issue of considerable controversy and should be undertaken in consultation with the neurologist who will be following the patient after discharge from the ED. Prompt treatment of any apparent ictal source discovered in the ED, however, is always appropriate.

**DISPOSITION**

Disposition plans must be individualized according to the findings of the ED evaluation and the presence or absence of underlying disease. One quarter of adult patients presenting with seizure-related complaints have new-onset seizures. Almost half of them require admission, most because of abnormal CT scans or persistent focal abnormalities; 95% of those who retrospectively required admission were correctly identified by using an ED evaluation consistent with that recommended previously. Patients may be discharged home with early referral to a neurologist if they have a normal neurologic exam, no comorbidities, no known structural brain disease, do not require the use of an antiepileptic drug in the ED, and are felt to be sufficiently resourceful and reliable to comply with follow-up instructions. Patients discharged home from the ED should receive appropriate state-specific guidance regarding driver’s license privileges and information for prompt follow-up with a neurologist.

PERSPECTIVE

Epidemiology
Up to 85% of the U.S. adult population complains of significant headaches at least occasionally, and 15% does so on a regular basis. Headache as a primary complaint represents between 3 and 5% of all emergency department (ED) visits. The vast majority of patients who have the primary complaint of headache do not have a serious medical cause for the problem. Tension headache accounts for approximately 50% of patients presenting to the ED, another 30% have headache of unidentified origin, 10% have migraine-type pain, and 8% have headache from other potentially serious causes (e.g., tumor, glaucoma). It is estimated that less than 1% of patients who present to the ED with headache have a life-threatening organic disease. The percentages can create a false sense of security, and headache is disproportionately represented in emergency medicine malpractice claims. Although still rare, the most commonly encountered life-threatening cause of severe sudden head pain is subarachnoid hemorrhage (SAH); approximately 20,000 potentially salvageable cases of SAH present to EDs each year. It is estimated that between 25 and 50% of these are missed on the first presentation to a physician. The other significant, potentially life-threatening causes of headache occur even less frequently. Meningitis, carbon monoxide poisoning, temporal arteritis, acute angle-closure glaucoma, intracranial hemorrhage (ICH), cerebral venous sinus thrombosis, and increased intracranial pressure can often be linked with specific historical elements and physical findings that facilitate their diagnosis.

Pathophysiology
The brain parenchyma is insensitive to pain. The pain-sensitive areas of the head include the coverings of the brain—the meninges—and the blood vessels, both arteries and veins supplying the brain, and the various tissues lining the cavities within the skull. The ability of the patient to specifically localize head pain is often poor. Much of the pain associated with headache, particularly with vascular headache and migraines, is mediated through the fifth cranial nerve. Such pain may proceed back to the nucleus and then be radiated through various branches of the fifth cranial nerve to areas not directly involved. A specific inflammation in a specific structure (e.g., periapical abscess, sinusitis, or tic douloureux) is much easier to localize than the relatively diffuse pain that may be generated by tension or traction headaches. Pains in the head and neck may easily overlap. They should be thought of as a unit when considering complaints of headache.

DIAGNOSTIC APPROACH

Differential Considerations
The differential diagnosis of headache is complex because of the large number of potential disease entities and the diffuse nature of many types of pain in the head and neck region (Table 16-1). However, in evaluating the patient with a headache complaint, the top priority is to exclude intracranial hemorrhage (SAH and ICH), meningitis, encephalitis, and mass lesions. Carbon monoxide is an exogenous toxin, the effects of which may be reversible by removing the patient from the source and administering oxygen. Carbon monoxide poisoning is a rare example of a headache in which a simple intervention may quickly improve a critical situation. On the contrary, returning the patient to the poisoned environment without a diagnosis could be lethal.

Rapid Assessment and Stabilization
If the patient presents in a critical or comatose state, initial stabilization, including airway management, is undertaken as indicated, preceded by a neurologic examination if at all possible. For purposes of the initial assessment, headache can be divided into two categories: accompanied by altered mental status and without altered mental status. Whenever a patient’s mental status is impaired, brain tissue is initially assumed to be compromised. The principles of care centered on cerebral resuscitation address the seven major causes of evolving brain injury: lack of substrate (glucose, oxygen), cerebral edema, intracranial mass lesion, endogenous or exogenous toxins, metabolic alterations (fever, seizure), ischemia, or elevated intracranial pressure.

Pivotal Findings

History
The history is the pivotal part of the workup for the patient with headache (Table 16-2).

1. The patient should be asked to describe the pattern and onset of the pain. Patients often relate frequent and recurrent headaches similar to the one they have

on this ED visit. A marked variation in headache pattern can signal a new or serious problem. The rate of onset of pain may have significance. Pain with rapid onset of a few seconds to minutes is more likely to be vascular in origin than pain that developed over several hours or days.

Almost all studies dealing with subarachnoid bleeding report that patients moved from the pain-free state to severe pain within seconds to minutes. The “thunder clap” or “lightning strike” headache is a real phenomenon, and this response to questioning may lead to the correct diagnosis of subarachnoid hemorrhage, even if the pain is improving at the time of evaluation.3

2. The patient’s activity at the onset of the pain may be helpful. Certainly, headaches that come on during severe exertion have a relationship to vascular bleeding, but again, there is enough variation to make assignment to any specific cause highly variable. The syndrome of coital or postcoital headache is well known, but coitus is also a common time of onset for SAH. These headaches require the same evaluation on initial presentation as any other exertion-related head pain. If the patient can recall the precise activity in which he or she was engaging at the time of the onset of the headache (e.g., “I was just getting up out of the chair to answer the doorbell”), sudden onset is extremely likely and evaluation for SAH is warranted.

3. If the patient or nonhospital medical personnel can relate a history of head trauma, the differential diagnosis and emergent causes have narrowed significantly. The considerations now focus on epidural and subdural hematoma, traumatic SAH, skull fracture, and closed-head injury (i.e., concussion and diffuse axonal injury).

4. Toxoplasmosis, cryptococcal meningitis, and abscess are considered higher in the differential in patients with a history of HIV or immunocompromised state. Although such entities are rare, it is important to remember that this subset of patients may have serious disease without typical signs or symptoms of systemic illness (e.g., fever and meningismus).

5. The intensity of head pain is difficult to quantify objectively. Almost all patients who present to the ED consider their headache to be “severe.” Use of a pain scale of 1 to 10 may help differentiate patients initially but has more value in monitoring their response to therapy.
6. The character of the pain (i.e., throbbing, steady), although sometimes helpful, may not be adequate to differentiate one type of headache from another.

7. The location of head pain is helpful when the patient can identify a specific area. It is useful to have the patient point or try to indicate the area of pain and the emergency physician to then properly examine that area. Unilateral pain is more suggestive of migraine or a localized inflammatory process in the skull (e.g., sinus) or soft tissue. Occipital headaches are classically associated with hypertension. Certainly, temporal arteritis, temporomandibular joint disease, dental infections, and sinus infections frequently have a highly localized area of discomfort. Meningitis, encephalitis, SAH, and even severe migraine, although intense in nature, are usually more diffuse in their localization.

8. Exacerbating or alleviating factors may be important. Patients whose headaches rapidly improve when they are removed from their environment may have carbon monoxide poisoning. Most other severe causes of head pain are not rapidly relieved or improved when patients get to the ED. Headaches on awakening are typically described with brain tumors. Intracranial infections, dental infections, and other regional causes of head pain tend not to be improved or alleviated before therapy is given.

9. Associated symptoms and risk factors may relate to the severity of headache but rarely point to the specific causes (Box 16-1). Nausea and vomiting are completely nonspecific. Migraine headaches, increased intracranial pressure, temporal arteritis, and glaucoma can all manifest with severe nausea and vomiting, as can some systemic viral infections with headache. Such factors may point toward the intensity of the discomfort but are not specific in establishing the diagnosis.

10. A prior history of headache, although helpful, does not rule out current serious problems. It is extremely helpful, however, to know that the patient has had a workup for severe disease. Previous ED visits, computed tomography (CT) magnetic resonance imaging, and other forms of testing should be inquired about. Patients with both migraine and tension headaches tend to have a stereotypical recurrent pattern. Adherence to these patterns is also helpful in deciding the degree to which a patient’s symptoms are pursued.

**Physical Examination**

Physical findings associated with various forms of headache are listed in Table 16-3.

**Ancillary Testing**

The vast majority of headache patients do not require additional testing (Table 16-4). The single largest consistent mistake made by emergency physicians in the workup of the headache patient is believing a single CT scan clears the patient of the possibility of SAH or other serious intracranial disease. The CT scan can miss 6 to 8% of patients with SAH, especially in patients with minor (grade I) SAH, who are most treatable. The sensitivity of CT for identifying SAH is reduced by nearly 10% for symptom onset greater than 12 hours and by almost 20% at 3 to 5 days. The basic approach to integrating CTs and lumbar puncture in the assessment of headache is outlined in Figure 16-1, 8,9

CSF, cerebrospinal fluid; CT, computed tomography; ENT, ear, nose, and throat.
or altered mental status, (4) true meningismus, (5) unexplained fever or bradycardia, (6) focal neurologic deficits on examination, (7) symptoms refractory to treatment or worsening under observation, (8) new onset of headache with exertion, or (9) history of HIV. These patients have the highest risk for significant disease.

In addition, a group of reliable “all clear signals” indicates patients who do not require further investigation when all are present: (1) previous identical headaches, (2) normal alertness and cognition by both examination and history of the event, (3) normal examination of the neck showing no meningismus, (4) normal vital signs, (5) normal or nonfocal neurologic examination, and (6) improvement under observation or with treatment.

Sequential evaluation and assessment of data are ongoing processes. Patients should be reevaluated while in the ED, and inconsistent findings may require a rapid review of the situation and rethinking of the diagnosis (Table 16-5).7

**MANAGEMENT**

**Empirical**

Patients with headache represent a spectrum of disease. Patients with headache need to receive triage for evaluation according to their symptoms. Clearly, patients with abnormal vital signs or altered mental status require evaluation before patients with less severe symptoms. If history and physical examination point toward potentially lethal causes, however, effort should be made to establish the diagnosis rapidly with ancillary testing. Pain treatment should be started early. The pain medication of choice depends on the particular patient, underlying vital signs, allergies, and general condition; but relief of pain is still an essential part of the physician’s job and should have little effect on the diagnostic workup.

**Specific**

Specific management for headache is described in Chapter 101. The challenge in emergency medicine, however, is to eliminate life-threatening causes of headache and to treat the patient’s pain.

**DISPOSITION**

Most patients presenting with headache are discharged from the ED with appropriate analgesia and follow-up. These represent patients in the all-clear category or those found to have no serious disease after a careful evaluation and testing. Any patients in whom warning findings are noted require more extensive assessment.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
**PERSPECTIVE**

*Dyspnea* is the term applied to the sensation of breathlessness and the patient's reaction to that sensation. It is an uncomfortable awareness of breathing difficulties that in the extreme manifests as “air hunger.” Dyspnea is often ill defined by patients, who may describe the feeling as shortness of breath, chest tightness, or difficulty breathing. Dyspnea results from a variety of conditions, ranging from nonurgent to life-threatening. Neither the clinical severity nor the patient’s perception correlates well with the seriousness of underlying pathology and may be affected by emotions, behavioral and cultural influences, and external stimuli.1,2

The following terms may be used in the assessment of the dyspneic patient:

- **Tachypnea**: A respiratory rate greater than normal. Normal rates range from 44 cycles/min in a newborn to 14 to 18 cycles/min in adults.
- **Hyperpnea**: Greater than normal minute ventilation to meet metabolic requirements.
- **Hyperventilation**: A minute ventilation (determined by respiratory rate and tidal volume) that exceeds metabolic demand. Arterial blood gases (ABG) characteristically show a normal partial pressure of oxygen (PO2) with an uncompensated respiratory alkalosis (low partial pressure of carbon dioxide [PCO2] and elevated pH).
- **Dyspnea on exertion**: Dyspnea provoked by physical effort or exertion. It often is quantified in simple terms, such as the number of stairs or number of blocks a patient can manage before the onset of dyspnea.
- **Orthopnea**: Dyspnea in a recumbent position. It usually is measured in number of pillows the patient must use to lie in bed (e.g., two-pillow orthopnea).
- **Paroxysmal nocturnal dyspnea**: Sudden onset of dyspnea occurring while reclining at night, usually related to the presence of congestive heart failure.

**Epidemiology**

Dyspnea is a common presenting complaint among emergency department patients of all ages. Causes vary widely and may be due to a benign, self-limited condition or significant pathology that can produce long-term morbidity and premature mortality.

**Pathophysiology**

The actual mechanisms responsible for dyspnea are unknown. Normal breathing is controlled both centrally by the respiratory control center in the medulla oblongata, as well as peripherally by chemoreceptors located near the carotid bodies, and mechanoreceptors in the diaphragm and skeletal muscles.3 Any imbalance between these sites is perceived as dyspnea. This imbalance generally results from ventilatory demand being greater than capacity.4

The perception and sensation of dyspnea are believed to occur by one or more of the following mechanisms: increased work of breathing, such as the increased lung resistance or decreased compliance that occurs with asthma or chronic obstructive pulmonary disease (COPD), or increased respiratory drive, such as results from severe hypoxemia, acidosis, or centrally acting stimuli (toxins, central nervous system events). Pulmonary stretch receptors also are thought to play a role.

**DIAGNOSTIC APPROACH**

**Differential Considerations**

Dyspnea is subjective and has many different potential causes.5 The differential diagnosis list can be divided into acute and chronic causes, of which many are pulmonary. Other etiologies include cardiac, metabolic, infectious, neuromuscular, traumatic, and hematologic (Table 17-1).

**Pivotal Findings**

**History**

- **Duration of Dyspnea**: Chronic or progressive dyspnea usually denotes primary cardiac or pulmonary disease.6 Acute dyspneic spells may result from asthma exacerbation; infection; pulmonary embolus; intermittent cardiac dysfunction; psychogenic causes; or inhalation of irritants, allergens, or foreign bodies.
- **Onset of Dyspnea**: Sudden onset of dyspnea should lead to consideration of pulmonary embolism (PE) or spontaneous pneumothorax. Dyspnea that builds slowly over hours or days may represent a flare of asthma or COPD; pneumonia; recurrent, small pulmonary emboli; congestive heart failure; or malignancy.

**Primarily Associated with Normal or Increased Respiratory Effort**

- Abdominal
  - Mechanical interference
  - Hypotension, sepsis from ruptured viscus, bowel obstruction, inflammatory/infectious process
- Psychogenic
- Metabolic/endocrine
  - Toxic ingestion
  - DKA
- Infectious
  - Epiglottitis
  - Pneumonia (CAP score < 70)
- Traumatic
  - Tension pneumothorax
  - Cardiac tamponade
  - Flail chest
- Hematologic
  - Carbon monoxide poisoning
  - Acute chest syndrome

**Primarily Associated with Decreased Respiratory Effort**

- Neuromuscular
  - CVA, intracranial insult
  - Organophosphate poisoning
  - Multiple sclerosis
  - Guillain-Barré syndrome
  - Tick paralysis
- ALS
  - Polymyositis
  - Porphyria

---

**Positional Changes.** Orthopnea can result from left-sided heart failure, COPD, or neuromuscular disorders. One of the earliest symptoms seen in patients with diaphragmatic weakness from neuromuscular disease is orthopnea. Paroxysmal nocturnal dyspnea is most common in patients with left-sided heart failure, but also can be found in COPD. Exertional dyspnea commonly is associated with COPD, but also can be seen with poor cardiac reserve and abdominal loading. Abdominal loading, caused by ascites, obesity, or pregnancy, leads to elevation of the diaphragm, resulting in less effective ventilation and dyspnea.

**Trauma.** Dyspnea can result from trauma, causing fractured ribs, flail chest, hemothorax, pneumothorax, diaphragmatic rupture, pericardial effusion, cardiac tamponade, or neurologic injury.

**Symptoms**

Patient descriptions of dyspnea vary significantly and generally correlate poorly with severity. Fever suggests an infectious cause. Anxiety may point to panic attack or psychogenic dyspnea, if no organic cause can be isolated. PE or myocardial infarction may present with isolated dyspnea or with associated chest pain, particularly if the pain is constant, dull, or visceral. If the pain is sharp and worsened by deep breathing but not by movement, pleural effusion and pleurisy or pleural irritation from pneumonia or PE are possible. Spontaneous pneumothorax also may produce sharp pain with deep breathing that is not worsened by movement.

**Signs**

Physical signs in dyspneic patients may be consistent with specific illnesses (Table 17-2). Physical findings in specific diseases also can be grouped as presenting patterns (Table 17-3).

**Ancillary Studies**

Specific findings obtained from the history and physical examination should be used to determine which ancillary studies are needed (Table 17-4). Bedside oxygen saturation determinations, or selective use of ABGs when oximetry is not reliable, are useful in determining the degree of hypoxia and the need for supplemental oxygen or assisted ventilation. An additional resource for quickly assessing ventilatory status is non-invasive waveform capnography. Using both the end-tidal CO2 value and the shape of the waveform itself can be helpful in assessing the adequacy of ventilations as well as potential causes of the dyspnea (See Chapter 3). An electrocardiogram may be useful if the etiology is cardiac or suggests acute pulmonary hypertension.

Serum electrolytes may suggest less common possible causes, such as hypokalemia, hypophosphatemia, diabetic ketoacidosis, or hypocalcemia. A complete blood count may identify severe anemia or thrombocytopenia associated with sepsis. The white blood cell count is not sufficiently sensitive or specific to be of discriminatory value. Cardiac markers and D-dimer assay may be useful in pursuing etiologies such as...

**DIFFERENTIAL DIAGNOSIS**

The range and diversity of pathophysiologic states that produce dyspnea make a simple algorithmic approach difficult. After initial stabilization and assessment, findings from the history, physical examination, and ancillary testing are collated to match patterns of disease that produce dyspnea. This process is updated periodically as new information becomes available. Table 17-3 presents recognizable patterns of disease for common dyspnea-producing conditions, along with specific associated symptoms.

### Critical Diagnoses

Several critical diagnoses should be promptly considered to determine the best treatment options to stabilize the patient. Tension pneumothorax is such a critical diagnosis. If a dyspneic patient has diminished breath sounds on one side, ipsilateral hyper-resonance, severe respiratory distress, hypotension, and oxygen desaturation, prompt decompression of presumptive tension pneumothorax is necessary. Bedside ultrasonography may assist in confirming pneumothorax. If obstruction of the upper airway is evidenced by dyspnea and stridor, early, definitive assessment and intervention must occur in the emergency department or operating room. Complete obstruction by a foreign body warrants the Heimlich maneuver until the obstruction is relieved or the patient is unconscious, followed rapidly by direct laryngoscopy. Congestive heart failure and pulmonary edema can produce dyspnea and respiratory failure and should be treated as soon as possible if severe. Significant dyspnea and wheezing can be seen in anaphylaxis and must be treated promptly to prevent further deterioration. Severe bronchospastic exacerbations of asthma at any age may lead rapidly to respiratory failure and arrest and should receive vigorous attention, including continuous or frequent administration of a beta-agonist aerosol. As mentioned earlier, waveform capnography is a valuable tool for assessing the severity and determining the cause of respiratory distress.

### Emergent Diagnoses

Asthma and COPD exacerbations can result in marked dyspnea with bronchospasm and decreased ventilatory volumes. Sudden onset of dyspnea with a decreased oxygen saturation on room air accompanied by sharp chest pain may represent PE. Dyspnea accompanied by decreased breath sounds and tympany to percussion on one side is seen with spontaneous pneumothorax. Dyspnea associated with decreased respiratory effort may represent a neuromuscular process, such as multiple sclerosis, Guillain-Barré syndrome, or myasthenia gravis. Unilateral rales, cough, fever, and dyspnea usually indicate pneumonia.

Figure 17-1 provides an algorithm for assessment and stabilization of a dyspneic patient. The initial division is based on the degree of breathing effort associated with the symptoms.
Figure 17-1. Rapid assessment and stabilization of a dyspneic patient. ABG, arterial blood gas; ACE, angiotensin-converting enzyme; BiPAP, biphasic positive airway pressure; BNP, B-type natriuretic peptide; CO, carbon monoxide; CPAP, continuous positive airway pressure; CT, computed tomography; CXR, chest x-ray; ECG, electrocardiogram; EtCO2, end-tidal carbon dioxide; IV, intravenous; JVD, jugular venous distention; NSSTWC, nonspecific ST wave changes (on ECG); PE, pulmonary embolism; RR, respiratory rate; V/Q, ventilation-perfusion ratio; U/S, ultrasound.

The most critical diagnoses must be considered first and appropriate intervention taken as necessary.

All patients experiencing dyspnea, regardless of possible cause, should be promptly transported to the treatment area. Bedside pulse oximetry should be obtained, and the patient should be placed on a cardiac monitor. If the pulse oximetry is less than 98% saturated on room air, the patient should be placed on supplemental oxygen either by nasal cannula or mask depending on the degree of desaturation detected. If necessary, the patient should be intubated, and breathing should be assisted with manual or mechanical ventilation.

When the airway has been secured, rapid assessment of the patient’s appearance and vital signs can help determine the need for further stabilization. Decreased mental alertness, inability to speak in more than one-word syllables, or certain types of body positioning, signal the presence of significant
Figure 17-2. Clinical guidelines for emergency department management of dyspnea. respiratory distress and the need for rapid intervention. After stabilization has occurred, the cause of the dyspnea can be further investigated.

**EMPIRICAL MANAGEMENT AND DISPOSITION**

The management algorithm for dyspnea (Fig. 17-2) outlines the approach to treatment for most identifiable diseases. Unstable patients or patients with critical diagnoses must be stabilized and may require admission to an intensive care unit. Emergent patients who have improved in the emergency department may be admitted to an intermediate care unit. Patients diagnosed with urgent conditions in danger of deterioration without proper treatment or patients with severe comorbidities, such as diabetes, immunosuppression, or cancer, may also require admission for observation and treatment.

Most patients in the nonurgent category can be treated as outpatients if good medical follow-up can be arranged. If dyspnea persists despite therapy and no definitive cause has been delineated, the best course of action is hospitalization for observation and ongoing evaluation. If no definitive diagnosis can be obtained and the symptoms have abated, the patient may be discharged with good medical follow-up and instructions to return if symptoms recur.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
PERSPECTIVE

Nearly 6 million patients present to the emergency department (ED) each year with complaints of chest pain, constituting 5% of all patients seen in EDs in the United States. Chest pain is a symptom caused by several life-threatening diseases and has a broad differential diagnosis. It is complicated by a frequent disassociation between intensity of symptoms and signs and seriousness of underlying pathology.

Epidemiology

The epidemiology of the critical diagnoses causing chest pain varies widely. Acute coronary syndromes (ACS), aortic dissection, pulmonary embolism (PE), pneumothorax, pericarditis with tamponade, and esophageal rupture are potentially catastrophic causes of chest pain. Due to its high incidence and potential lethality, ACS is the most significant potential diagnosis in the ED. Of all deaths in the United States, 36% are attributed to cardiovascular diseases; these account for approximately 870,000 deaths per year. Historically, emergency physicians misdiagnose 3 to 5% of myocardial infarctions (MIs), accounting for 25% of malpractice losses in emergency medicine. Thoracic aortic dissection has an incidence of 0.5 to 1 per 100,000 population with a mortality rate exceeding 90% if misdiagnosed. The true incidence of PE is unclear, with estimates of 70 per 100,000. This equates to approximately 100,000 PE cases per year in the United States. Although the incidence of tension pneumothorax is also unclear, the incidence of spontaneous pneumothorax ranges from 2.5 to 18 per 100,000 total patients. The total incidence of esophageal rupture is 12.5 cases per 100,000 persons. The true incidence of pericarditis is unknown, but is diagnosed in 1 of every 1000 hospital admissions. Up to 5% of ED chest pain patients without acute ST elevation MI may have pericarditis.

Pathophysiology

Afferent fibers from the heart, lungs, great vessels, and esophagus enter the same thoracic dorsal ganglia. Through these visceral fibers, each organ produces the same indistinct quality and location of pain. The quality of visceral chest pain varies widely and is described as “burning,” “aching,” “stabbing,” or “pressure.” Since dorsal segments overlap three segments above and below a level, disease of a thoracic origin can produce pain anywhere from the jaw to the epigastrium. Radiation of pain is caused by somatic afferent fibers synapsing in the same dorsal root ganglia as the thoracic viscera. This stimulation can “confuse” the patient’s central nervous system into misperceiving that the pain originates in the arms or shoulders.

DIAGNOSTIC APPROACH

Differential Considerations

Due to the indistinct nature of visceral pain, the differential diagnosis of chest pain is broad and includes many of the most critical diagnoses in medicine and many nonemergent conditions (Table 18-1).

Rapid Stabilization and Assessment

The initial questions are, “Must I intervene immediately?”, and “What are the life-threatening possibilities in this patient?” The answers are usually apparent within the first few minutes after assessing the patient’s appearance and vital signs. One of the critical diagnoses is tension pneumothorax. If a patient presents with chest pain, respiratory distress, shock, and unilateral reduction or absence of breath sounds, immediate intervention with needle or tube thoracostomy is required. Additionally, patients with severe derangements in vital signs require stabilizing treatment during a search for the precipitating cause. Patients who present with respiratory distress require immediate intervention and lead the emergency physician to consider a more serious cause of the pain (Fig. 18-1; also see Chapter 17). All patients, except those with obvious benign causes of chest pain, must have an electrocardiogram (ECG) within minutes of reporting their pain. This ECG should be read for acute MI by the emergency physician as soon as it is completed. Patients with positive ECG findings and those considered at high risk are triaged directly to the treatment area and monitored. Symptomatic derangements in vital signs are addressed. If vital signs are stable, a focused history and physical examination are performed. Most patients also require a chest radiograph to evaluate the chest pain. If a cardiac cause is suggested and vital signs are stable, pain relief with nitroglycerin (0.4 mg sublingual every 3–5 minutes) may be appropriate. Aspirin (81–325 mg) is a consideration for patients without hemorrhagic disorders, known allergies, or vascular dissections. Clopidogrel (loading dose 300 mg) or other anti-
are key to diagnosis. Information pertinent to the differential diagnosis is obtained by the history, physical examination, and ECG in 80 to 90% of patients.

**History**

1. The patient is asked to describe the character of the pain or discomfort. Descriptions such as “squeezing,” “crushing,” or “pressure” lead the emergency physician to suspect a cardiac ischemic syndrome, although cardiac ischemia can also be characterized by nonspecific discomfort, such as “bloating” or “indigestion.” “Tearing” pain that may migrate from the front to back or back to front is the classic description in aortic dissection. “Sharp” or “stabbing” pain is seen more in pulmonary and musculoskeletal diagnoses. Patients complaining of a “burning” or “indigestion” type of pain may initially be thought to have a gastrointestinal etiology, but due to the visceral nature of chest pain, all causes of pain may present with any of the preceding descriptions. Of note, descriptors may vary among ethnic groups, and, for example, “sharp” may mean “severe.”

2. Additional history about the patient’s activity at the onset of pain may be helpful. Pain occurring during exertion suggests an ischemic coronary syndrome, whereas progressive onset of pain at rest suggests acute MI. Pain of sudden onset is more typical with aortic dissection, PE, or pneumothorax. Pain after meals is more indicative of a gastrointestinal cause.

3. The severity of pain is commonly quantified using a 1-to-10 pain scale. Alterations in pain severity are documented at times of onset, peak, present, and after intervention.

4. The location of the discomfort is described. Pain that is localized to a small area is more likely to be somatic versus visceral in origin. Pain localized at the periphery of the
chest is more likely with a pulmonary rather than cardiac etiology. Lower chest or upper abdominal pain may be of cardiac or gastrointestinal origin.

5. Any description of radiation of pain should be noted. Transthoracic pain through to the back should suggest aortic dissection or gastrointestinal causes, especially pancreatitis or posterior ulcer. Inferioposterior myocardial ischemia may also present primarily as thoracic back pain. Radiation to the arms, neck, or jaw increases the likelihood of cardiac ischemia. Pain located primarily in the back, especially interscapular back pain that migrates to the base of the neck, suggests aortic dissection.

6. Duration of pain is another important historical factor. Pain that lasts a few seconds is rarely of cardiac origin. Pain that is exertional but lasts for only a few minutes after rest may be a manifestation of cardiac ischemia. Pain that is maximal at onset may be due to aortic dissection. Pain that is not severe and persists over the course of days is less likely to be of serious origin than pain that is severe or has a stuttering or fluctuating course.

7. The clinician should consider aggravating or alleviating factors. Pain that worsens with exertion and improves with rest is more likely related to coronary ischemia. Pain related to meals is more suggestive of a gastrointestinal cause. Pain that worsens with respiration is seen more often with pulmonary, pericardial, and musculoskeletal causes.

8. Other associated symptoms may suggest the visceral nature of the pain (Table 18-2). Diaphoresis should lead to an increased clinical suspicion for a serious or visceral cause. Hemoptysis, a classic PE sign, is rarely seen. Near-syncope and syncope lead to higher likelihood of a cardiovascular cause or PE. Dyspnea is seen in cardiovascular and pulmonary disease. Nausea and vomiting may be seen in cardiovascular and gastrointestinal complaints.

9. A history of prior pain and the diagnosis of that episode can facilitate the diagnostic process, but the physician must be wary of prior presumptive diagnoses that may be misleading. A prior history of cardiac testing, such as stress testing, echocardiography, or angiography, may be useful in determining if the current episode is suggestive of cardiac disease. Similarly, patients with previous spontaneous pneumothorax or PE are at increased risk of recurrence.

10. The presence of risk factors for a particular disease is primarily of value as an epidemiologic marker for large population studies (Box 18-1). In the ED, presence of risk factors in an individual patient without established disease has minimal or no effect on the clinical likelihood (pretest probability) of a specific disease process.

**Physical Examination**

Specific findings may be found in a variety of causes (Table 18-3).

**Ancillary Studies**

The two most commonly performed studies in patients with chest pain are the chest radiograph and 12-lead ECG (Table 18-4). An ECG should be performed within 10 minutes of arrival in all patients with chest pain in whom myocardial ischemia is a possibility. This generally includes all male patients 33 years old and older and female patients over the age of 39 who complain of pain from the umbilicus to the mandible unless a noncardiac cause is readily apparent. Rapid acquisition of the ECG facilitates the diagnosis of acute MI and expedites the National Heart, Lung, and Blood Institute’s recommended “door to treatment” times from arrival to percutaneous coronary intervention (PCI) or thrombolytic therapy in acute MI. Patients with a new injury pattern on ECG (Table 18-5) or new ischemic ECG changes should have appropriate therapy instituted at this point (Fig. 18-2; see also Chapter 77). An ECG showing right ventricular strain pattern, in the appropriate setting, should raise the clinical suspicion for PE. Diffuse ST segment elevation helps make the diagnosis of pericarditis.

A chest radiograph is performed for patients with a possibly serious cause of chest pain. Pneumothorax is definitively diagnosed at this point. A wide mediastinum or ill-defined aortic knob increases the clinical suspicion for acute aortic dissection. Pleural effusion, subcutaneous air, or mediastinal air-fluid...

LBBB, left bundle-branch block.

level may be seen in esophageal rupture. Increased cardiac silhouette may indicate pericarditis or cardiomyopathy.

Pneumomediastinum is seen with esophageal rupture and mediastinitis. A serum D-dimer assay may help discriminate patients with PE from those with a possible gastrointestinal cause. A low serum D-dimer in a patient without a high pretest probability of PE effectively excludes the diagnosis.\(^{13,17,18}\) (see Chapter 87.)

Patients at high pretest probability for PE should undergo diagnostic imaging (multidetector computed tomography [CT], or, less commonly, pulmonary angiography or a ventilation-perfusion lung scan).\(^{19}\) High pretest probability warrants initiation of anticoagulation (heparin or low-molecular-weight heparin) therapy in the ED before the imaging study, in the absence of a contraindication.

Patients with suspected thoracic aortic dissection may be evaluated by CT angiography, transesophageal echocardiography, or magnetic resonance imaging. Selection of imaging modality depends on patient status and availability of the testing equipment.\(^{20}\)

CT with a 64 or higher detector scanner has the potential to rule out all of the life-threatening causes of chest pain. Although the “triple rule out” of ACS, PE, and thoracic dissection are the causes most commonly discussed, pneumothorax, mediastinitis, and pericardial effusions are also diagnosed with CT.\(^{21,22}\)

<tr>
<td><strong>Myocardial Infarction</strong></td>
<td>Discomfort is usually moderately severe to severe and rapid in onset. May be more &quot;pressure&quot; than pain. Usually retrosternal, may radiate to neck, jaw, both arms, upper back, epigastrium, and sides of chest (left more than right). Lasts more than 15–30 min and is unrelieved by NTG</td>
<td>Diaphoresis, nausea, vomiting, dyspnea</td>
<td>May be precipitated by emotional stress or exertion. Often comes on at rest. May come on in early awakening period. Prodromal pain pattern often elicited. Previous history of MI or angina. Age &gt;40 years, positive risk factors, and male sex increase possibility</td>
<td>Common</td>
<td>Patients are anxious and uncomfortable. Blood pressure usually is elevated, but normotension and hypotension are seen. The heart rate is usually mildly increased, but bradycardia can be seen. Patients may be diaphoretic and show peripheral poor perfusion. There are no diagnostic examination findings for MI, although S(_3) and S(_4) heart sounds and new murmur are supportive</td>
<td>ECG changes (new Q waves or ST segment–T wave changes) occur in 80% of patients. CK-MB and troponins are helpful if elevated, but may be normal</td>
</tr>
<tr>
<td><strong>Unstable Angina</strong></td>
<td>Changes in pattern of preexisting angina with more severe, prolonged, or frequent pain (crescendo angina). Pain usually lasts &gt;10 min. Angina at rest lasting 15–20 min or new-onset angina (duration &lt;2 mo) with minimal exertion. Pattern of pain change important in gauging risk for AML. Unpredictable responses to NTG and rest</td>
<td>Often minimal. May have mild diaphoresis, nausea, dyspnea with pain. Increasing pattern of dyspnea on exertion</td>
<td>Not clearly related to precipitating factors. May be a decrease in amount of physical activity that initiates pain. Previous history of MI or angina. Over 40 years old, presence of risk factors, and male sex increase probability</td>
<td>Common</td>
<td>Nonspecific findings of a transient nature, may have similar cardiac findings as in MI, especially intermittent diaphoresis</td>
<td>Often no ECG or enzyme changes. Variant angina (Prinzmetal’s) has episodic pain, at rest, often severe, with prominent ST segment elevation</td>
</tr>
</tbody>
</table>
### Aortic Dissection

- **90% of patients** have rapid-onset severe chest pain that is maximal at beginning. Radiates anteriorly in chest to the back interscapular area or into abdomen. Pain often has a “tearing” sensation, and may migrate.

- **Neurologic complications of stroke, peripheral neuropathy, paresis or paraplegia, abdominal and extremity ischemia possible.**

- **Median age 59 years.** History of hypertension in 70–90% of patients. 3:1 ratio males to females. Marfan’s syndrome and congenital bicuspid aortic valves have increased incidence.

- **Rare**

- **Often poorly perfused peripherally but with elevated BP. In 50–60% of cases, there is asymmetrical decrease or absence of peripheral pulses. 50% of proximal dissections cause aortic insufficiency. Other vascular occlusions: coronary (1–2%), mesentery, renal, spinal cord. New-onset pericardial friction rub or aortic insufficiency murmur supportive of diagnosis.

- **ECG usually shows left ventricular hypertrophy, nonspecific changes. Chest film shows abnormal aortic silhouette (90%).**

- **Aortic angiography has diagnostic accuracy of 95–99%. Transesophageal echocardiogram, CT, MRI most useful in screening.**

- **Ascending aortic aneurysms are more often approached surgically. Descending are generally managed medically.**

### Pulmonary Embolism

- **Pain is more often lateral-pleuritic. Central pain is more consistent with massive embolus. Abrupt in onset and maximal at beginning. May be episodic or intermittent.**

- **Dyspnea and apprehension play a prominent role, often more than pain. Cough accompanies about half the cases.**

- **Hemoptysis occurs in <20%. Angina-like pain may occur in 5%.**

- **Often some period of immobilization has occurred, e.g., postoperative. Pregnancy, oral contraceptives, heart disease, and cancer are all risk factors. Previous DVT or PE is the greatest risk factor.**

- **Uncommon in ambulatory patients, but common in departments with high volumes of elderly or medically complex patients.**

- **Patients are anxious and often have a respiratory rate >16/min. Tachycardia, inspiratory rales, and an increased pulmonary second sound are common. Fever, plebitis, and diaphoresis are seen in 30–40% of patients. Wheezes and peripheral cyanosis are less common.**

- **Arterial blood gases show \( P_{O_2} < 80 \text{ mm Hg} \) in 90%. Widened A-a gradient is helpful. Chest film is usually normal, although 40% show some volume loss, oligemia, or signs of consolidation due to pulmonary infarction. Lung perfusion scan rules out, if truly negative.**

- **Patients may present with dyspnea with or without bronchospasm. Acute mortality rate is 10%. Emboli usually from lower extremities above knee, prostate/pelvis venous plexus, right heart. May be subtle cause of COPD exacerbation.**

AMI, acute myocardial infarction; CK-MB, an isoenzyme of creatine kinase; COPD, chronic obstructive pulmonary disease; CT, computed tomography; DVT, deep vein thrombosis; ECG, electrocardiogram; MRI, magnetic resonance imaging; NSAID, nonsteroidal anti-inflammatory drug; NTG, nitroglycerin; PE, pulmonary embolus; SLE, systemic lupus erythematosus.
Laboratory testing is useful in the evaluation of ACS. Creatine kinase (CK) is associated with multiple false-positive results and has no use in the evaluation of unstable angina. CK-MB, an isoform of CK, is more specific for cardiac ischemia. Evaluating this enzyme produces fewer false-positive results, and peak sensitivity approaches 98%. Sensitivity at 4 hours is, however, only about 60%. CK-MB isoforms improve sensitivity at 4 hours to 80%, approaching 93% at 6 hours. The current universal definition of MI places CK and CK-MB in a secondary role to troponins.

Troponins (I and T), when elevated, identify patients with ACS who have the highest risk for an adverse outcome. Sensitivity for acute MI at 4 hours is 60%, rising to nearly 100% by 12 hours. Elevated troponin in the correct clinical setting is synonymous with acute MI and is embedded in the universal definition of MI.

**DIAGNOSTIC TABLE**

After the patient is stabilized and assessment has been completed, the findings are matched to the classic and atypical patterns of the seven potentially critical diseases causing chest pain. This matching process is continual while evaluating the patient and monitoring the response to therapy. Any inconsistency in findings with the primary working diagnoses requires a rapid review of the pivotal findings and the potential diagnoses (Table 18-6).

**MANAGEMENT AND DISPOSITION**

The management of ACS is discussed in Chapter 76. Figure 18-3 outlines the approach to treatment of critical noncardiac diagnoses. Patients with critical diagnoses generally are admitted to the intensive care unit. Patients with emergent diagnoses typically are admitted to the hospital, most often on telemetry units. Patients with nonemergent diagnoses are most frequently treated as outpatients. Hospitalization is required in certain circumstances, particularly when patients have other comorbid conditions.

Frequently, no definitive diagnosis is established. Any patient with almost any type of chest pain may be having coronary ischemia, PE, or aortic dissection. When a clear pattern does not emerge to allow the emergency physician to make an alternative diagnosis confidently, continued evaluation, hospitalization, or observation admission may be the best course.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
PERSPECTIVE

Syncope is the sudden transient loss of consciousness with a loss of postural tone. It is a common presenting complaint in the emergency department (ED). Despite improved understanding of risk and outcomes, consensus on diagnostic approach and disposition remains elusive. This is in part due to its varied causes and lack of definitive diagnostic studies, and in part because of confusion and lack of standard terminology to describe the disorder.1 Diagnostic accuracy relies largely on the synthesis of patient risk factors and reported symptoms, with limited reliance on the physical examination and ancillary testing.

Epidemiology

The prevalence of syncope in the general population is approximately 19%.2 Patients present to the ED at a rate of 2.8 visits per 1000 population, which accounts for 0.8% of ED visits.2,3 Approximately 32% of these patients are admitted, and syncope accounts for 1 to 6% of all hospitalized patients.2,4 Persons aged 65 years and older account for 80% of such admissions.5 In the pediatric population, 15% experience at least one episode of syncope.6

Risk factors for syncope include cerebrovascular disease, cardiac medications, and hypertension.7 Most causes of syncope are benign and have favorable outcomes. Patients with pre-existing cardiovascular disease and syncope from any cause are at the greatest short- and long-term risk of mortality.8,9 Syncope from cardiovascular causes carries a long-term hazard ratio of death of 2.41 when adjusted for age and sex.9 In contrast, there is no increased risk of cardiovascular morbidity or mortality associated with syncope from neurocardiogenic, orthostatic, and medication-related syncope.8 Recurrence of syncope may be as high as 50% and is not correlated with age or sex.2

Benign causes of syncope predominate in adolescents and young adults. Approximately 30% of athletes dying during exercise, however, have had a prior episode of syncope as a sentinel event.9 Prospective outcome studies in children are lacking, but most reports suggest that mortality rates are very low.9 Significant trauma may result from syncope and can contribute to increased risk of mortality and morbidity, particularly in the elderly.10,11 The overall U.S. medical cost of syncope is estimated at $2.4 billion annually.12

Pathophysiology

The final common pathway resulting in syncope is dysfunction of either both cerebral hemispheres or the brainstem (reticular activating system), usually from acute hypoperfusion. Reduced blood flow may be regional (cerebral vasoconstriction) or systemic (hypotension).13 Loss of consciousness results in loss of postural tone, with the resulting syncopal episode. Less severe derangements may result in sensations of presyncope or light-headedness. In this fashion, presyncope and syncope may be considered on a continuum with shared etiologies and mechanisms. By definition, syncope is transient; therefore, the cause of central nervous system (CNS) dysfunction must likewise be transient.8,14 Persistent causes of significant CNS dysfunction result in coma or depressed consciousness (See Chapter 14).

Hypoperfusion resulting in approximately 35% or more reduction in cerebral blood flow usually produces unconsciousness, and any mechanism that adversely affects the components of perfusion (cardiac output, systemic vascular resistance, blood volume, regional vascular resistance) can cause or contribute to syncope. Other mechanisms of CNS dysfunction resulting in syncope include hypoglycemia, toxins, metabolic abnormalities, failure of autoregulation, and primary neurologic derangements.

DIAGNOSTIC APPROACH

Differential Considerations

The potential causes of syncope are numerous and can be categorized according to their primary mechanism (Box 19-1). The first differential diagnostic consideration is to distinguish syncope from other causes of an apparent sudden loss of consciousness, especially seizure and uncommon disorders such as cataplexy. When syncope has been established as the working diagnosis, the life-threatening causes, primarily cardiovascular in origin, are considered first. The principal serious causes of syncope are dysrhythmias and myocardial ischemia.15 Cerebrovascular disease, principally subarachnoid hemorrhage, is less frequently encountered, but equally serious. Toxic-metabolic abnormalities may induce syncope through alterations in blood pressure or cardiac rhythm. Structural cardiac lesions, such as critical aortic stenosis, and sudden
interruption of right ventricular outflow by pulmonary embolism can also cause sudden loss of consciousness. Dissection of the thoracic aorta rarely manifests primarily as syncope, but is potentially catastrophic.

Pivotal Findings

The majority of cases of syncope arise from benign causes, so the evaluation is largely focused on excluding serious pathology. Young, healthy patients with clearly benign syncope may require no formal diagnostic evaluation other than a thorough history and physical examination. The yield of an electrocardiogram (ECG) is generally low; however, it is recommended because it is noninvasive and relatively inexpensive. The clinical examination alone can suggest the diagnosis in 45% of cases. Nevertheless, up to 50% of patients may not have a clear diagnosis for their syncope after an initial evaluation in the ED.

Symptoms

Symptoms can often suggest the diagnosis, although the value of the history diminishes in older patients. The patient is asked to describe the character of the syncopal event. Witnesses may be able to supplement and corroborate the patient’s incomplete recall, and that history should be solicited. Key characteristics include the rate of onset (gradual or abrupt), position on symptom onset (e.g., standing, sitting, or supine), and duration and rate of recovery. Abrupt onset, occurrence while sitting or supine, and duration of more than a few seconds are usually ascribed to serious, often cardiac, causes of syncope. Similarly, incomplete or near-syncope may be less serious, but at least one study suggests that onset associated with a prodrome or presyncope may herald cardiac origin. The diagnostic approach to presyncope, however, is the same as for syncope.

Events during the syncopal episode do not usually clarify the cause. Tonic-clonic movements, related to inadequate cerebral perfusion, can occur in any form of syncope, including benign neurocardiogenic syncope, and must be differentiated from the prolonged activity with subsequent postictal depression of consciousness seen in seizure disorders (see Chapter 19 for a detailed discussion).

Cardinal Presentations

— except in young, otherwise healthy patients with a clear history and setting for benign neurocardiogenic (vasovagal) syncope.16,17 Although the yield is low, the ECG is noninvasive and relatively inexpensive, and may be revealing.18 New ischemic ECG changes are indicative of acute coronary ischemia and

Neuropathic agents (vincristine)

Nonsteroidal anti-inflammatory drugs

Bromocriptine

Signs

The physical examination focuses primarily on the elements affecting the cardiovascular and neurologic systems.20 Specific findings are detailed in Table 19-1. Signs of orthostasis should be sought in all cases where this mechanism is suggested.21 Carotid massage to detect carotid sinus hypersensitivity is both safe and occasionally revealing; it is probably underutilized. Rectal examination for gross blood or melena is recommended if anemia or gastrointestinal bleed is possible.

Ancillary Studies

The chief diagnostic adjunct in evaluating syncope is the 12-lead ECG (Table 19-2). It is warranted in all cases of syncope

HEENT, head, eyes, ears, nose, and throat.
warrant appropriate therapy. Dysrhythmias and shortened PR or prolonged QT intervals may be identified on the 12-lead ECG. A right bundle branch block in association with ST elevation in leads V1 through V3 suggests Brugada’s syndrome. Unanticipated cardiac hypertrophy may be revealed. Continuous limb-lead ECG monitoring in the ED may also identify transient dysrhythmias. An ECG showing right ventricular strain pattern may suggest pulmonary embolism, whereas diffuse ST elevation or electrical alternans help diagnose pericarditis associated with pericardial tamponade.

Routine blood, serum, and urine studies have limited utility in the evaluation of syncope and are generally unrewarding. When suggested by the history and physical examination, however, selective use of the hemogram, serum electrolytes and glucose, urine drug screen, and pregnancy test may identify or exclude some uncommon causes of syncope. Radiographic studies including cranial computed tomography offer limited yield in most cases of syncope, and unless abnormalities are identified on neurological examination, are not routinely indicated.

In otherwise healthy patients for whom a benign dysrhythmia, such as rapid supraventricular tachycardia or atrial fibrillation, is suggested, Holter or preferably event ECG monitoring may be helpful. In patients with significant underlying cardiac disease or when a significant dysrhythmia is a possible cause of the syncope, echocardiography, continuous monitoring, or cardiovascular stress-testing may be helpful in the inpatient or ED observation unit setting. Depending on the results of initial evaluation, electrophysiologic studies, or magnetic resonance imaging may be indicated. Electroencephalography has a low yield unless seizure is suggested. Tilt table testing, although infrequently used in the United States, may have diagnostic value in elderly patients and children in whom chronic orthostatic hypotension is possible.

Although not technically an ancillary study, formal psychiatric evaluation deserves mention as a potential diagnostic tool in syncope. In patients with compatible symptoms and signs or negative medical evaluation and recurrent episodes of syncope, psychiatric evaluation may be revealing.

### DIAGNOSTIC ALGORITHM

The critical diagnoses to consider are listed in Table 19-3. The emergent causes of syncope are protean and are included in Box 19-1. Many other causes such as neurocardiogenic and reflex-mediated syncope have benign mechanisms.

After stabilization and assessment, the clinical features coupled with onset and recovery suggest the cause (Table 19-4). A logical approach to the history, physical examination, and diagnostic testing is depicted in Figure 19-1. The emphasis is on risk stratification since short-term mortality risk in syncope

\section*{EMPIRICAL MANAGEMENT}

\textbf{Rapid Assessment and Stabilization}

Syncope is by definition a transient event so most patients are
asymptomatic on presentation. Patients with significantly
abnormal vital signs, recurrent syncope, or associated symp­
toms of a concerning nature such as chest pain or shortness of
breath should undergo rapid evaluation.

\textbf{Diagnosis and Management}

Most patients presenting with syncope require confirmatory
bedside diagnostic evaluation. The 12-lead ECG is the prin­
cipal tool for evaluating cardiac causes of syncope. Orthostatic
vital signs, although unreliable as an evaluation of volume
status, may be helpful when positional changes are accompa­
nied by typical presyncopal symptoms and a significant fall in
heart rate or blood pressure.\textsuperscript{23} A schematic of selected diagnost­
ic testing strategies for syncope is depicted in Figure 19-2.

Patients with critical diagnoses are generally admitted to the
intensive care unit (ICU). Those with emergent diagnoses are
typically admitted to telemetry units. Patients with nonemer­
gent diagnoses can be treated as outpatients.

Several scoring systems aid in the admission decision­
making process, most notably the San Francisco Syncope
Rule.\textsuperscript{27} In essence, this guideline suggests that in the absence
of abnormal ECG findings, shortness of breath, hypotension
(systolic < 90 mm Hg), anemia (hematocrit < 30\%), or a history
of congestive heart failure, the patient is at sufficiently low risk
to consider outpatient disposition. The San Francisco Syncope
Rule as well as other proposed rules, however, require external
validation before widespread application.\textsuperscript{4,28-31}

Hospitalization is required for patients with chest pain,
unexplained shortness of breath, a history of significant con­
gestive heart failure, or valvular disease.\textsuperscript{14,18,32} Patients with
ECG evidence of ventricular dysrhythmias, ischemia, signifi­
cantly prolonged QT interval, or new bundle branch block are
also admitted.\textsuperscript{14,17,38} The clinician should consider monitoring
patients with any of the following indications: age older than
45 years, preexisting cardiovascular or congenital heart disease,
family history of sudden death, serious comorbidities such as
diabetes, or exertional syncope.\textsuperscript{17,18,25,32}

The ED evaluation of syncope is often inconclusive. After
a history, physical examination, and 12-lead ECG, up to 50%
of patients do not have a firm diagnosis.\textsuperscript{19,32} Patients younger
than 45 years and without worrisome symptoms, signs, or ECG
findings are generally at lower risk for adverse outcome and
may often be treated as an outpatient. Discharged patients
should be warned of the hazards of recurrent syncope occur­
ing during activities such as driving or working at heights.\textsuperscript{17}
Figure 19-2. Diagnosis algorithm for syncope.

Nausea and vomiting may constitute the primary presentation of many gastrointestinal (GI) disorders (e.g., bowel obstruction, gastroenteritis) or the secondary presentation of numerous systemic conditions (1) caused by severe pain, especially visceral pain; (2) caused by or related to severe systemic illness, such as myocardial infarction, sepsis, or shock; or (3) related to definitive conditions by specific mechanisms, such as pregnancy (hormones), increased intracranial pressure (central mechanism), toxins (homeostatic response), motion sickness (neuroendocrine), and chemotherapy (chemoreceptor trigger zone [CTZ]). Additionally, vomiting may cause serious sequelae, such as aspiration pneumonia, Mallory-Weiss syndrome, esophageal rupture, volume depletion, and metabolic derangement. Classification by duration and frequency of the vomiting (acute, recurrent, chronic, or cyclic) may assist in determination of the underlying cause.1

Epidemiology

The most common causes of nausea and vomiting are acute gastroenteritis, febrile systemic illnesses, and drug effects. Acute viral gastroenteritis is the most common GI disease in the United States. In adult medicine, nausea and vomiting are caused most often by medications. Emesis associated with pregnancy is common, especially in the first trimester, but hyperemesis gravidarum is not. Although the scope of the differential diagnosis in the pediatric population is broad, acute vomiting is commonly seen with infectious disorders affecting the gastrointestinal tract as well as with infections in other areas of the body.2

Pathophysiology

The act of vomiting can be divided into three distinct phases: nausea, retching, and actual vomiting3 (Fig. 20-1). Nausea may occur without retching or vomiting, and retching may occur without vomiting. Nausea is defined as a vague and extremely unpleasant feeling that often precedes vomiting. The exact neural pathways mediating nausea are not clear, but they are likely to be the same pathways that mediate vomiting. Mild activation of the pathways may result in nausea, whereas more intense stimulation results in vomiting. During nausea, there is an increase in tone in the musculature in the duodenum and jejunum, with a concomitant decrease in gastric tone; this leads to reflux of intestinal contents into the stomach. There is often associated hypersalivation, repetitive swallowing, and tachycardia.

Retching is characterized as rhythmic, synchronous contractions of the diaphragm, abdominal muscles, and intercostals that occur against a closed glottis. There is a resultant increase in abdominal pressure with a concurrent decrease in intrathoracic pressure. This pressure gradient causes gastric contents to move up into the esophagus. The mouth is usually closed.

Vomiting is the forceful expulsion of gastric contents through the mouth. There is contraction of the external oblique and abdominal rectus muscles, and the hiatal portion of the diaphragm relaxes; this increases the pressure in the abdominal and the thoracic compartments. There is contraction of the pyloric portion of the stomach. Simultaneously, there is relaxation of the gastric fundus, cardia, and upper esophageal sphincter as the vomitus is brought up and out the mouth. The glottis closes to prevent aspiration.

The complex act of vomiting is not completely understood but is thought to be coordinated by a vomiting center located in the lateral reticular formation of the medulla (Fig. 20-2). The efferent pathways from the vomiting center are mainly through the vagus, phrenic, and spinal nerves. These pathways are responsible for the integrated response of the diaphragm, intercostals, abdominal muscles, stomach, and esophagus. The vomiting center is activated by afferent stimuli from a variety of sources. These include vagal and sympathetic impulses directly from the GI tract. Direct irritation of the stomach lining causes vomiting in this way. Other GI sources of afferent impulses include the pharynx, small bowel, colon, biliary system, and peritoneum. Receptors also are found outside the GI tract in the vestibular system, heart, and genitalia.

The other major source of impulses to the vomiting center is the CTZ. The CTZ is located in the area postrema, the floor of the fourth ventricle. Part of this area is located outside of the blood-brain barrier, enabling it to respond to endogenous and exogenous substances that activate vomiting. It is activated by hormones, peptides, medications, or toxins in the circulation, including opiates, digitalis, chemotherapy agents, salicylate, syrup of ipecac, and dopamine neurotransmitters.

The discovery of various neurotransmitters and their receptor sites within the medulla has improved the understanding and development of therapeutic agents. The CTZ area is rich in dopamine D2 receptors, which are antagonized by drugs such as prochlorperazine, metoclopramide, and droperidol. The serotonin receptor has been found widely in the area postrema and the GI tract. It may act directly and through the release of dopamine. The serotonin receptor antagonists ondansetron and granisetron have been shown to be effective in preventing chemotherapy-induced nausea and vomiting. Concentrations of cholinergic and histamine receptors are found in the lateral vestibular nucleus and are important in

PERSPECTIVE

Leslie S. Zun and Amardeep Singh

Chapter 20

Nausea and Vomiting
motion sickness. Meclizine, diphenhydramine, and scopolamine act by antagonizing these receptors. Cannabinoid receptors have been found to inhibit the emetic reflex.

**Rumination** is regurgitation of ingested food that subsequently is reswallowed or ejected. Rumination syndrome is found in infants, children, and mentally challenged adults, but rarely in adults with normal intelligence.

**DIAGNOSTIC APPROACH**

**Differential Considerations**

The differential diagnosis for nausea and vomiting is particularly broad in scope; almost any organ system can be involved (Table 20-1). Vomiting also can result in complications, which must be considered in addition to the causes. The sequelae of vomiting may include the following various metabolic and traumatic lesions.

**Hypovolemia** is caused by loss of water and sodium chloride in the vomitus. The contraction of the extracellular fluid space leads to activation of the renin-angiotensin-aldosterone system.

**Metabolic alkalosis** is produced by loss of hydrogen ions in the vomitus. Many factors serve to maintain the alkalosis, including volume contractions, hypokalemia, chloride depletion, shift of extracellular hydrogen ions into cells, and increased aldosterone.

**Hypokalemia** is produced primarily by loss of potassium in the urine. The metabolic alkalosis leads to large amounts of sodium bicarbonate being delivered to the distal tubule. Secondary hyperaldosteronism from volume depletion causes
reabsorption of sodium and excretion of large amounts of potassium in the urine.

Mallory-Weiss tears typically result from a forceful bout of retching and vomiting. The lesion itself is a 1- to 4-cm tear through the mucosa and submucosa; 75% of cases occur in the stomach, with the remainder near the gastroesophageal junction. Bleeding usually is mild and self-limited; however, 3% of deaths from upper GI bleeds are due to Mallory-Weiss tears.

Boerhaave's syndrome refers to a perforation of all layers of the esophagus occurring as a result of forceful retching or vomiting. The overlying pleura is torn so that there is free passage of esophageal contents into the mediastinum and thorax; 80% of cases involve the posterolateral aspect of the distal esophagus. Boerhaave’s syndrome constitutes a surgical emergency. The mortality rate is 50% if surgical repair is not performed within 24 hours.

Aspiration of gastric contents is a concern in patients who have altered mental status or pulmonary findings after an episode of vomiting. Patients with pulmonary findings after vomiting need further evaluation for aspiration.

Rapid Assessment and Stabilization

The initial assessment is directed toward the patient’s hemodynamic status and identifying the critical causes or sequelae of vomiting (see Table 20-1). Data gathered include duration of vomiting, whether blood is in the vomitus, symptoms of volume depletion, and associated symptoms pointing to serious underlying disease. Physical findings include level of consciousness, abdominal examination, rapid neurologic screen for focality, and serial vital signs. Initial stabilization may include establishing intravenous access and fluid resuscitation in patients with signs of volume depletion, cardiac monitoring, and therapeutic measures directed toward specific underlying diseases (e.g., blood pressure control in severe hypertension).

Pivotal Findings

A thorough history and physical examination usually yield the underlying cause of nausea and vomiting.

CNS, central nervous system; DKA, diabetic ketoacidosis; ICP, intracranial pressure.
**History**

*Duration of the vomiting* can lead to a diagnosis. *Acute* vomiting is occurring for less than 1 week and is associated with obstructive, ischemic, toxic, metabolic, infectious, neurologic, and postoperative causes. *Chronic* vomiting occurs with partial obstructions, motility disorders, and neurologic conditions or may be pregnancy-related or functional in origin.

*Timing of the vomiting* may be important. An acute onset of nausea and vomiting suggests gastroenteritis, pancreatitis, cholecystitis, or a drug-related side effect. Symptoms occurring primarily in the morning suggest pregnancy, although this pattern also may be seen with uremia, alcohol ingestion, or increased intracranial pressure. Delayed vomiting more than 1 hour after eating suggests gastric outlet obstruction or gastroparis. Vomiting of material eaten more than 12 hours previously is pathognomonic for outlet obstruction. Nausea and vomiting for more than 1 month are considered chronic. Discrete episodes of intractable vomiting with intervening asymptomatic periods are considered cyclic.

*Content of the vomitus* may provide clues. The presence of bile indicates a patent connection between the duodenum and the stomach and essentially rules out a gastric outlet obstruction. Regurgitation of undigested food can suggest achalasia, esophageal stricture, or Zenker’s diverticulum. Feculent material usually suggests a distal bowel obstruction but also may be seen with gastrocolic fistula or bacterial overgrowth of stomach contents in long-standing outlet obstruction.

*Associated symptoms and signs* may be helpful. Hypersalivation, defecation, tachycardia, bradycardia, atrial fibrillation, and termination of ventricular tachyarrhythmias are associated phenomena with nausea and vomiting. Chronic headaches with nausea and vomiting should raise the index of suspicion for an intracranial lesion. Also, vomiting without preceding nausea is typical of central nervous system pathology. The *social history* should include inquiries about alcohol or other substance abuse. The *past medical history* will reveal the presence of any GI disease or previous surgeries. Nutritional history is valuable in the consideration of failure to thrive in infancy. Finally, a thorough *medication list*, including over-the-counter drugs, should be included.

### Physical Examination

The important physical examination findings are outlined in Table 20-2. During evaluation, findings of jaundice, lymphadenopathy, vertigo, fever, and goiter can help determine the etiology of the disease. Oral examination may reveal loss of dental enamel commonly seen with bulimia. Abdominal examination may reveal ascites, distention, hernias, abdominal tenderness and masses, organomegaly, or hyper- or hypoactive bowel sounds, with appropriate laboratory testing for occult blood in the stool. Determination of orthostatic vital signs may be valuable in patients with signs of dehydration, light-headedness, generalized weakness, or toxic appearance. It also is important to evaluate neurologic status to rule out a central cause of a patient’s symptoms, which includes cranial nerves, funduscopic examination, and gait observation. Provocative testing for vertigo such as with the Nylan-Bárány test may elicit nausea and vomiting. Attentive physicians may elicit evidence of depression or anxiety that may lead to a psychiatric diagnosis.

In children, the examination should search for other diagnostic clues. A bulging fontanelle (meningitis), projective vomiting (pyloric stenosis), unusual odors (metabolic), visible bowel loops (obstruction), enlarged parotid, and loss of dental enamel (bulimia) point to specific etiologic disorders. Most of these disorders are age-dependent.

### Ancillary Studies

Because of the broad differential diagnosis for nausea and vomiting, there is no standard panel of laboratory tests. Appropriate testing is determined by the specifics of the history and

physical examination. The following general guidelines regarding specific tests are useful.

**Complete blood count:** Most patients do not require a complete blood count. Elevated hemoglobin may suggest dehydration, but other tests are better for this purpose. An elevated white blood count is entirely nonspecific and of no discriminatory value.

**Serum electrolytes:** Measurement of serum electrolytes is not indicated in most cases of vomiting. Severe, protracted vomiting can cause a hypochloremic, hypokalemic metabolic alkalosis. Patients with this history or with clinical evidence of dehydration should undergo electrolyte testing. In general, serum electrolyte testing is indicated only in patients with symptoms lasting longer than 3 days or signs of significant dehydration who require intravenous fluid to replenish vascular volume.

**Blood urea nitrogen and creatinine:** Classically a blood urea nitrogen-to-creatinine ratio greater than 20:1 implies significant dehydration.

**Serum lipase:** Lipase determination is indicated in cases of suspected pancreatitis.

**Urine tests:** A urine pregnancy test should be performed in all women of childbearing age. Nitrites, leukocyte esterase, white blood cells, and bacteria indicate a urinary tract infection. Ketones may support a diagnosis of diabetic ketoacidosis or prolonged starvation state. Hematuria indicates a possible renal calculus.

**Cultures:** Blood cultures may be indicated in the fever patient with nausea and vomiting. Urine cultures may be necessary to determine an underlying cause, and stool cultures looking for enteric pathogens, parasites, or leukocytes may be valuable.

**Liver function tests and ammonia tests:** Liver function tests are indicated in cases of suspected hepatitis or biliary disease. Ammonia testing is useful if liver failure is suspected.

**Serum drug levels:** Serum drug levels may be important in patients on theophylline, digoxin, or salicylates, especially in elderly patients who are taking medication without supervision.

**Abdominal imaging:** Flat and upright plain radiographs are indicated only in cases of suspected bowel obstruction or ileus. Computed tomography (CT) scan of the abdomen has supplanted plain radiography for the evaluation of many patients with suspected obstruction because of the improved ability to discern the cause of the problem in addition to the presence of obstruction. An abdominal ultrasound study is indicated in cases of suspected cholecystolithiasis or cholecystitis in adults, and suspected pyloric stenosis and intussusception in children. Imaging studies such as cranial CT scan or magnetic resonance imaging (MRI) may be needed for evaluation of possible central nervous system (CNS) trauma, tumor, or infectious causes.

**Electrocardiogram:** An electrocardiogram (ECG) is indicated in cases of suspected coronary artery ischemia.

**Thyroid function tests:** Although not usually available during the patient’s stay in the emergency department (ED), thyroid function tests may indicate a thyroid cause for the vomiting.

### Table 20-3

**Differential Diagnosis**

Clinical and diagnostic findings are helpful in differentiating among the common and catastrophic causes of nausea and vomiting (Table 20-3). The differential diagnosis in adults is extensive; etiologic categories include medication-induced, infectious and toxic causes, disorders of the gastrointestinal tract, CNS causes, pregnancy-related, endocrine and metabolic disorders, radiation-induced, postoperative, unknown (as in cyclic vomiting), psychogenic, and other causes such as acute myocardial infarction and acute graft-versus-host disease.

### Pediatric Considerations

The evaluation and management of pediatric patients with nausea and vomiting depend on age and likely causative disorders (Table 20-4). Mild degrees of reflux and associated regurgitation are common in the first few months of life, but vomiting in infancy can be associated with life-threatening illness. In the first week of life, obstructive lesions of the alimentary tract, inborn errors of metabolism, and serious infectious processes are associated with vomiting. After the first week of life, pyloric stenosis needs to be considered. The diagnosis of “feeding problems” should be considered a diagnosis of exclusion. After the first month of life, infections, metabolic diseases, cow’s milk intolerance, failure to thrive, and subdural hematoma from abuse should be prime considerations. Thereafter, various disorders are associated with vomiting, including recurrent cyclic vomiting, acute surgical emergencies, food poisoning, toxic ingestion, Henoch-Schönlein purpura, pneumonia, and diabetic ketoacidosis. Anorexia nervosa and bulimia should be considered in teenagers with recurrent vomiting.

### Management

If an underlying cause for the nausea and vomiting is discovered, treatment of this disorder would take precedence. Decreased oral intake is a major cause of dehydration and malnutrition. If the patient is able to take oral liquids, sports drinks are preferred while avoiding citrus and highly sweetened drinks. Patients who are dehydrated and in whom intake of oral fluids is not possible or is contraindicated should be given intravenous fluids. Hypokalemia is rarely of clinical significance but may be found with profound vomiting secondary to contraction metabolic alkalosis. Treatment of the underlying condition with administration of intravenous fluids is indicated. Placement of a nasogastric tube is an option in cases such as persistent vomiting, gastroparesis, pancreatitis, and bowel obstruction.

Pharmacologic management of patients with nausea and vomiting is outlined in Figure 20-2. To allow the physician to make an appropriate choice for each patient, the pharmacologic therapies available may be classified into histamine antagonists, muscarinic antagonists, dopamine antagonists, and serotonin antagonists.

The phenothiazines are widely used as general-purpose antiemetics. These agents have multiple complex mechanisms of action. The antiemetic effect is apparently through blockade of the dopamine D₂ receptor in the CTZ. Prochlorperazine (Compazine), droperidol (Inapsine), haloperidol (Haldol), and promethazine (Phenergan) are commonly used medications in this class. Mild to moderate side effects are fairly common and include dystonic reactions and feelings of restlessness. These side effects may be treated with diphenhydramine (Benadryl) or benztrapine (Cogentin). Although prochlorperazine was found to be more effective in reducing vomiting than promethazine, use of prochlorperazine has been reported to be associated with a 16% incidence of akathisia and a 4% incidence of dystonia, so patients should be advised about this potential and its mitigation with diphenhydramine or benztrapine. Neuroleptic malignant syndrome, blood dyscrasias, and cholestatic jaundice have been documented rarely with use of phenothiazines.

The serotonin receptor antagonists, such as ondansetron, granisetron, and tropisetron, are a class of agents that have

<tr>
<td>Bowel obstruction</td>
<td>Classically, abdominal pain consists of intermittent cramps occurring at regular intervals. The frequency of the cramps varies with the level of the obstruction; the higher the level, the more frequent the cramps. The location of the pain also varies with the level of the obstruction; high obstruction causes epigastric pain, mid-level obstruction causes periumbilical pain, colonic obstruction causes hypogastric pain.</td>
<td>Common</td>
<td>Abdominal distention, mild diffuse tenderness, and high-pitched “tinkling” bowel sounds may be present. Thorough search for hernias should be performed.</td>
<td>Supine and upright plain abdominal films Abdominal CT</td>
<td>Adhesions, hernias, and tumors account for 90% of bowel obstructions. Other causes include intussusception, volvulus, foreign bodies, gallstone ileus, inflammatory bowel disease, stricture, cystic fibrosis, and hematoma.</td>
</tr>
<tr>
<td>Carbon monoxide (CO) poisoning</td>
<td>Headache is usually present. CO poisoning often occurs during winter months when furnaces are turned on. Family members may have similar symptoms if they also have been exposed.</td>
<td>Uncommon</td>
<td>No reliable signs of early CO poisoning</td>
<td>CO level</td>
<td>Because CO is a tasteless, odorless gas, patients may not realize they have been exposed. It is important to keep a high index of suspicion during the winter months.</td>
</tr>
<tr>
<td>Boerhaave’s syndrome</td>
<td>Patients may have neck, chest, or epigastric pain. Forceful, protracted vomiting usually causes the tear. Most cases follow a bout of heavy eating and drinking. Other reported causes include childbirth, defecation, seizures, and heavy lifting.</td>
<td>Uncommon</td>
<td>Tachypnea, tachycardia, and hypotension may be present. Escaped air from the esophagus may produce subcutaneous emphysema. Air in the mediastinum produces a “crunching” sound as the heart beats (Hamman’s sign).</td>
<td>CXR may show pleural effusion, widened mediastinum, pneumothorax, or pneumomediastinum. Esophagogram using water-soluble contrast is definitive.</td>
<td>The classic presentation includes forceful vomiting, severe chest pain, subcutaneous emphysema, and multiple CXR findings. There is a growing body of evidence that most cases do not have this “classic” picture. In more subtle presentations, the diagnosis can be difficult to make.</td>
</tr>

**Abbreviations:** ABGs, arterial blood gases; AST, aspartate aminotransferase; β-hCG, β-human chorionic gonadotropin; BUN, blood urea nitrogen; CK, creatine kinase; CT, computed tomography; CXR, chest radiography; DKA, diabetic ketoacidosis; ECG, electrocardiogram; ERCP, endoscopic retrograde cholangiopancreatography; ETOH, ethyl alcohol; LDH, lactate dehydrogenase; MI, myocardial infarction; NSAID, nonsteroidal anti-inflammatory drug; PUD, peptic ulcer disease; WBC, white blood cell.
generated much interest because of their beneficial effect in chemotherapy-induced emesis. Their principal site of action is the area postrema, although they also affect receptors in the GI tract. Several studies in small series of patients have looked at their effect in overdose of theophylline and acetaminophen. With both of these agents, overdose causes vomiting, and oral therapy is often prevented effective oral therapy in patients with overdose of theophylline and acetaminophen. These studies showed that ondansetron inhibited vestibular stimulation and vestibular pathways. Their anticholinergic effect also may contribute to their effectiveness in vertigo and motion sickness. These effects are usually mild and transient.

Antihistamines are useful in nausea and vomiting associated with motion sickness and vertigo. Agents such as dimenhydrinate (Gravol, Dramamine) and meclizine (Antivert) directly inhibit vestibular stimulation and vestibular-cerebellar pathways. Their anticholinergic effect also may contribute to their effectiveness in vertigo and motion sickness. Antihistamines have some role as general antiemetics but are better used in the prevention of motion sickness; for nausea and vomiting, they are less effective than the phenothiazines. Antiemetics used in patients with isolated gastric motility disorders. The most common side effects of metoclopramide are restlessness, drowsiness, and diarrhea. These effects are usually mild and transient.

Antihistamines are useful in nausea and vomiting associated with motion sickness and vertigo. Agents such as dimenhydrinate (Gravol, Dramamine) and meclizine (Antivert) directly inhibit vestibular stimulation and vestibular-cerebellar pathways. Their anticholinergic effect also may contribute to their effectiveness in vertigo and motion sickness. Antihistamines have some role as general antiemetics but are better used in the prevention of motion sickness; for nausea and vomiting, they are less effective than the phenothiazines. The most common side effects of antihistamines are drowsiness, blurred vision, dry mouth, and hypotension. The newer, less-sedating antihistamines are thought to be less effective as antiemetics.

IM, intramuscular; IV, intravenous.
The anticholinergic agent scopolamine in a transdermal patch (Transderm Scōp) or hyoscine (Buscapan) in an oral form may be used for prophylaxis and treatment of motion sickness. These agents also have mild efficacy in preventing cytotoxic chemotherapy-related nausea and vomiting but are not useful in the emergency department.

Benzodiazepine medications have been used for nausea and vomiting, with variable results. Limited studies have evaluated the efficacy of benzodiazepines in the treatment of hyperemesis gravidarum, in prophylaxis for emetogenic chemotherapy, and preoperatively for minor gynecologic surgery. Although this aspect was not directly measured in these studies, the studies inferred that part of the response may be related to the anxiolytic component. No studies have addressed the use of benzodiazepines to treat nonspecific nausea and vomiting in an ED population.

Many of the new medications for nausea and vomiting are first tested as agents for prevention and treatment related to chemotherapy and postoperative nausea and vomiting (PONV). A new oral neurokinin-1 antagonist, aprepitant (Emend), has been found to be an effective adjunctive agent for use in patients receiving cancer chemotherapy. Aprepitant blocks the effects of substance P in the brain. Currently, it is not indicated for use in patients with established nausea and vomiting.

The medication choice is directed at the underlying cause of the nausea and vomiting, if known, such as motion sickness, PONV, or nausea and vomiting related to cancer chemotherapy. For all other patients, the choice of antiemetic agent has not been well studied in emergency medicine. One study found droperidol to be more effective than prochlorperazine or metoclopramide as compared with placebo for moderate to severe nausea of any cause. The same limitation is true of preferred agents used in the field. One study found that ondansetron was moderately effective in the treatment of nausea and vomiting in this setting.

As with adults, the underlying cause of nausea and vomiting is first addressed in determining treatment choices. Most of the same agents used in adults are recommended for children in a weight-based dosing regimen. Ondansetron and metoclopramide have value for antiemetic treatment to reduce nausea and vomiting in pediatric patients. These agents are particularly effective in improving gastroenteritis patients’ ability to maintain oral hydration.

**Special Situations**

Medications such as antihistamines are frequently used to reduce the incidence of nausea and vomiting when opioid analgesics are administered in the ED for pain control. Studies have demonstrated that the incidence of nausea and vomiting related to opioid administration in the ED is low and that these medications have little efficacy in reducing nausea and vomiting.

Many agents have been advocated for the treatment of nausea and vomiting in pregnancy (NVP). The treatments include nonpharmacologic—avoiding triggers, dietary changes, acupun­
ture apейчасер, ginger, and behavioral therapy—and pharmacologic—pyridoxine, antihistamines, metoclopramide, ondansetron, or prochlorperazine. Hyperemesis gravidarum is treated essentially as for NVP. For mild symptoms, pyridoxine (vitamin B6), acupressure, ginger, and administration of antiemetics including antihistamines, metoclopramide, ondansetron, prochlorperazine, and phenothiazines may be used. Pyridoxine, acupressure, and ginger are thought to be of benefit but are not commonly used in the ED. For severe symptoms, hospitalization, fluids, corticosteroids, and electrolyte replacement may be needed. No specific medication has been shown to be superior in the treatment of hyperemesis gravidarum.

Treatment of PONV is well known. Approximately one third of the patients undergoing surgery may experience nausea and vomiting unless they receive appropriate prophylactic treatment, and the incidence is surgical procedure-dependent. Droperidol, metoclopramide, ondansetron, and dexamethasone have been used to reduce PONV. However, the need for antiemetic therapy during procedural sedation in the ED is not well studied. Many of the same drugs associated with PONV used by anesthesiologists in the operating room are used in the ED for procedural sedation. Nitrous oxide and propofol have been associated with a higher incidence of nausea and vomiting. Although the optimal medication for PONV has yet to be determined, ondansetron is considered a first-line agent in some studies; this recommendation could be extended to postprocedural sedation–related nausea and vomiting in the ED.

Chemotherapy-related nausea and vomiting may be seen in the ED. The chemotherapy-induced nausea and vomiting may be acute (up to 24 hours) or delayed (after 24 hours). The incidence of nausea and vomiting is correlated with the emetic potential of the chemotherapeutic agents, the patient’s risk factors and other comorbid disorders, and antiemetic treat­
ment. Patients commonly are given the serotonin antagonists dexamethasone and aprepitant for both immediate and delayed prophylaxis. Cannabinoids also have been used to control chemotherapy-induced nausea and vomiting. Choice of agents for treatment in the ED has not been studied, but for this indication the serotonin antagonists and apreptants are used.

**DISPOSITION**

Hospital admission is appropriate when the patient has a significant underlying disease, has an unclear diagnosis and responds poorly to fluid and antiemetic therapy, continues to experience uncontrolled emesis refractory to medication, or is at the extremes of age with poor response to treatment. A category subject to broad interpretation is patients in whom the diagnosis is unclear and prospects for timely follow-up are poor (e.g., the patient has no family physician, lacks transportation, is indigent, habitually abuses drugs or alcohol, or has a language barrier). Discharge may be considered if no serious underlying illness is present, the response to fluid and antiemetic therapy is good, the patient is able to take clear liquids before discharge, and the prospects for follow-up and observation at home are favorable.

Close follow-up is arranged for most discharged patients, preferably with their primary care physician, in 24 to 48 hours. At discharge, the patient is prescribed medications as needed and is advised to restart oral intake with small feedings of a liquid diet with gradual return to a normal diet. Some experts have recommended the nausea and vomiting diet, which requires the least amount of gastric neuromuscular work. It is a three-step diet: Sports drinks and bouillon are recommended in step 1; soups are recommended in step 2; and foods that require the least amount of gastric “work” are recommended in step 3, such as meals high in protein and low in lipids. Clear instructions are given to return to the emergency department if there is a recurrence, change, or deterioration in symptoms.

Causes of nausea and vomiting frequently remain undiagnosed. Some cases declare themselves or resolve over time; reevaluation and close follow-up are imperative for patients with continuing symptoms. In patients with persistent or recurring symptoms, psychogenic causes or cyclic vomiting syndrome should be considered.

CHAPTER 21 Abdominal Pain
Rimon N. Bengiamin, Gavin R. Budhram, Kelly E. King, and John M. Wightman

PERSPECTIVE

Abdominal pain is a common emergency department (ED) complaint but, for many reasons, is often diagnostically challenging. The nature and quality of abdominal pain may be difficult for the patient to convey. Physical examination findings with this complaint are variable and can be misleading. The location and severity of the pain may change over time. Benign-appearing symptoms and presentations may evolve into life-threatening conditions. Conversely, patients presenting with severe symptoms may carry a relatively benign diagnosis. All of these factors make evaluation of patients with acute abdominal pain challenging in the ED setting.

Epidemiology

Abdominal pain is a common presenting complaint, accounting for up to 10% of all ED visits. Some of the most common causes of acute abdominal pain are listed in Table 21-1. Many patients present with pain and other symptoms that are not typical of any specific disease process. A specific diagnosis may not be possible in about one in every four individuals presenting with this chief complaint.1 In addition, several adult groups deserve special consideration: the elderly (older than 65 years of age), the immunocompromised, and women of reproductive age.

Elderly patients with acute abdominal pain are more likely to have a life-threatening process as the cause of their pain. Conditions such as diverticulitis, ruptured abdominal aneurysm, or mesenteric ischemia may manifest atypically and be rapidly progressive. Decreased diagnostic accuracy, coupled with increased probability of severe disease, results in increased mortality in elderly patients with abdominal pain.2

Increasingly, emergency physicians are seeing patients in immunocompromised states secondary to HIV/AIDS, chemotherapy, and immunosuppressive drugs. For many reasons, these patients also prove challenging. Their clinical presentation can be misleading owing to atypical physical and laboratory findings, such as lack of fever or elevated white count. In regard to infection, the scope of the differential diagnosis also should be broader than usual.3–5 Presentations in the immunocompromised patient may be highly variable and subtle and are discussed in Chapter 181.

The evaluation of abdominal pain in women involves a differential diagnosis of considerable extent and often requires a more in-depth physical exam and further diagnostic testing. Pelvic organs may be the source of significant pathology in both the pregnant and the nonpregnant patient. The possibility of ectopic pregnancy in women of reproductive age greatly increases the risk of serious disease with a high potential for misdiagnosis. During pregnancy the uterus becomes an abdominal rather than a pelvic organ and may displace the normal intraperitoneal contents, adding complexity to the evaluation of these patients.6 Nonpregnant patients require evaluation for various ovarian and uterine pathology states.

Pathophysiology

Pathology in the gastrointestinal and genitourinary tracts remains the most common source of pain perceived in the abdomen. Also, pain can arise from a multitude of other intra-abdominal and extra-abdominal locations (Box 21-1). Abdominal pain is derived from one or more of three distinct pain pathways: visceral, somatic, and referred.

Visceral pain results from stimulating autonomic nerves invested in the visceral peritoneum surrounding internal organs. It is often the earliest manifestation of a particular disease process. Distention of hollow organs by fluid or gas and capsular stretching of solid organs from edema, blood, cysts, or abscesses are the most common stimuli. This discomfort is poorly characterized and difficult to localize. If the involved organ is affected by peristalsis, the pain often is described as intermittent, crampy, or colicky. In general, visceral pain is perceived from the abdominal region that correlates with the embryonic somatic segment:

- Foregut structures (stomach, duodenum, liver, and pancreas) are associated with upper abdominal pain.
- Midgut derivatives (small bowel, proximal colon, and appendix) are associated with periumbilical pain.
- Hindgut structures (distal colon and genitourinary tract) are associated with lower abdominal pain.

Visceral pain can be perceived in a location remote from the actual disease process. Localization occurs with the extension of the disease process beyond the viscera. A classic example is that of the early periumbilical pain of appendicitis (midgut). When the parietal peritoneum becomes involved, the pain localizes to the right lower quadrant of the abdomen, the usual location of the appendix.

Somatic pain occurs with irritation of the parietal peritoneum. This is usually caused by infection, chemical irritation, or another inflammatory process. Sensations are conducted by

<tbody>
<tr>
<td>Gastric, esophageal, or duodenal inflammation</td>
<td>Occurs in all age groups.</td>
<td>Caused by gastric hypersecretion, breakdown of mucoprotective barriers, infection, or exogenous sources.</td>
<td>Epigastric radiating or localized, associated with certain foods. Pain may be burning. In some cases, exacerbation in supine position.</td>
<td>Epigastric tenderness without rebound or guarding. Perforation or bleeding leads to more severe clinical findings.</td>
<td>Uncomplicated cases are treated with antacids or histamine H₂ blockers before invasive studies are contemplated. Gastroduodenoscopy is valuable in diagnosis and biopsy. Testing for H. pylori with blood or biopsy specimens. If perforation is suspected, an upright chest radiograph is obtained early to rule out free air. CT may be beneficial.</td>
</tr>
<tr>
<td>Acute appendicitis</td>
<td>Peak age in adolescence and young adulthood; less common in children and elders. Higher perforation rate in women, children, and elders and in pregnancy. Mortality rate is 0.1% but increases to 2–6% with perforation.</td>
<td>Appendiceal lumen obstruction leads to swelling, ischemia, infection, and perforation.</td>
<td>Epigastric or periumbilical pain migrates to RLQ over 8–12 hr (50–60%). Later presentations associated with higher perforation rates. Pain, low-grade fever (15%), and anorexia (80%) common; vomiting less common (50–70%).</td>
<td>Mean temperature 38°C (100.5°F). Higher temperature associated with perforation. RLQ tenderness (90–95%) with rebound (40–70%) in majority of cases. Rectal tenderness in 30%.</td>
<td>Leukocyte count usually elevated or may show left shift. Urinalysis may show sterile pyuria. CT is sensitive and specific. US may have use in women, pregnancy, and children with RLQ pain.</td>
</tr>
<tr>
<td>Biliary tract disease</td>
<td>Peak age 35–60 yr; rare in patients younger than 20. Female-to-male ratio of 3:1. Risk factors include multiparity, obesity, alcohol intake, and use of birth control pills.</td>
<td>Passage of gallstones causes biliary colic. Impaction of a stone in cystic duct or common duct causes chocecytitis or cholangitis.</td>
<td>Crampy RUQ pain radiates to right subcapsular area. Prior history of pain is common. May have nausea or postprandial pain. Longer duration of pain favors diagnosis of chocecytitis or cholangitis.</td>
<td>Temperature normal in biliary colic, elevated in chocecytitis and cholangitis. RUQ tenderness, rebound, and jaundice (less common) may be present.</td>
<td>WBC count elevated in chocecytitis and cholangitis. Lipase and liver function tests may help differentiate this from gastritis or ulcer disease. Ultrason shows wall thickening, pericholecystic fluid, stones, or duct dilatation. Hepatobiliary scintigraphy diagnoses gallbladder function.</td>

<tr>
<td>Diverticulitis</td>
<td>Incidence increases with advancing age, affects males more often than females. Recurrences are common. Often called &quot;left-sided&quot; appendicitis.</td>
<td>Colonic diverticula may become infected or perforated or cause local colitis. Obstruction, peritonitis, abscesses, fistulas result from infection or swelling.</td>
<td>Pain usually poorly localized, intermittent, crampy, and diffuse. Diarrhea is key element in diagnosis; usually large-volume, watery. Nausea and vomiting usually begin before pain.</td>
<td>Abdominal examination usually nonspecific without peritoneal signs. Watery diarrhea or no stool noted on rectal examination. Fever is usually present.</td>
<td>Acute gastroenteritis</td>
</tr>
<tr>
<td>Acute gastroenteritis</td>
<td>Common diagnosis. Seasonal. Most common misdiagnosis of appendicitis. May be seen in multiple family members. History of travel or immune compromise.</td>
<td>Usually viral. Consider invasive bacterial or parasitic in prolonged cases, in travelers, or immune-compromised patients.</td>
<td>Abdominal pain; change in bowel habits.</td>
<td>Radiographs may show large amounts of stool. This is a diagnosis of exclusion.</td>
<td>Acute gastroenteritis</td>
</tr>
<tr>
<td>Constipation and obstipation</td>
<td>More common in females, the elderly, the very young, and patients on narcotics.</td>
<td>Idiopathic or hypokinesis secondary to disease states (low motility) or exogenous sources (diet, medications).</td>
<td>Abdominal pain; change in bowel habits.</td>
<td>Radiographs may show large amounts of stool. This is a diagnosis of exclusion.</td>
<td>Constipation and obstipation</td>
</tr>
<tr>
<td>Nonspecific abdominal pain</td>
<td>More common in persons of young and middle age, women of childbearing age or persons of low socioeconomic status, and patients with psychiatric disorders. Up to 10% of patients older than 50 years of age will have intra-abdominal cancer.</td>
<td>Unknown. Early or undiagnosed presentation of pathologic conditions.</td>
<td>Variable but tends to be chronic or recurrent.</td>
<td>Variable but no peritoneal signs. Rectal exam should be done to evaluate for subtle signs of pathology, including heme-positive stool, fistulas, and fissures.</td>
<td>Nonspecific abdominal pain</td>

the peripheral nerves and are better localized than the visceral pain component. Figure 21-1 illustrates some more typical pain locations corresponding to specific disease entities. Somatic pain is often described as intense and constant. As disease processes evolve to peritoneal irritation with inflammation, better localization of the pain to the area of pathology generally occurs.

Referred pain is defined as pain felt at a distance from its source because peripheral afferent nerve fibers from many internal organs enter the spinal cord through nerve roots that also carry nociceptive fibers from other locations, as illustrated in Figure 21-2. This makes interpretation of the location of noxious stimuli difficult for the brain. Both visceral pain and somatic pain can manifest as referred pain. Two examples of referred pain are the epigastric pain associated with an inferior myocardial infarction and the shoulder pain associated with blood in the peritoneal cavity irritating the diaphragm. Gynecologic and obstetric presentations are discussed in other chapters. Notably, any abdominal pain in a female may represent referred pain from pelvic structures or an extension of a pelvic process, as in the case of perihepatic inflammation with pelvic inflammatory disease.

### Diagnostic Approach

The clinical approach should focus on early stabilization, history, physical examination, and any ancillary tests collectively facilitating appropriate management and disposition plans.

### Differential Considerations

Classically, potential diagnoses are divided into intra-abdominopelvic (intraperitoneal, retroperitoneal, and pelvic) causes (e.g., appendicitis, cholecystitis, pancreatitis) and extra-abdominopelvic processes (e.g., pneumonia, myocardial infarction, ketoacidosis).

Although significant morbidity and mortality can result from many disorders causing abdominal pain, a few processes warrant careful consideration in the ED. Table 21-2 lists important potentially life-threatening nontraumatic causes of abdominal pain. This group represents the major etiologic disorders likely to be associated with hemodynamic compromise and for which early therapeutic intervention is critical.

### Rapid Assessment and Stabilization

As with any complaint, triage is the first critical step in management. Most patients presenting with abdominal pain do not have hemodynamic instability, but up to 7% of these patients may have a life-threatening process. This percentage is higher in elders and immunocompromised patients. Physiologically compromised patients should be brought to a treatment area immediately and resuscitation initiated. Profound shock or protracted emesis can lead to airway compromise necessitating intubation. These patients are often severely volume depleted and require rapid intravenous access and volume resuscitation with an isotonic crystalloid solution, titrated to a physiologic endpoint. Extreme conditions such as ruptured abdominal aortic aneurysm, massive gastrointestinal hemorrhage, ruptured spleen, and hemorrhagic pancreatitis may require blood or blood product replacement. Bedside ultrasonography can be used to quickly evaluate patients for free intraperitoneal fluid, volume status, and presence of aortic pathology. Ultrasound assessment should be part of the initial physical examination and can be invaluable in guiding treatment and disposition. Because any of the immediately life-threatening entities may necessitate surgical intervention or management, early surgical consultation is indicated.

### Pivotal Findings

#### History

A careful and focused history is central to unlocking the puzzle of abdominal pain. Box 21-2 lists some historical questions with high yields for serious pathology. Language and cultural differences may influence accurate communication and mutual understanding. Abrupt onset often is indicative of a more serious cause; however, delayed presentations also may represent a surgical condition. Surgical causes of abdominal pain are more likely to manifest with pain first, followed by nausea and vomiting, rather than with nausea and vomiting followed by pain. Localization and pain migration also are helpful components of the pain history. Diffuse pain generally is nonsurgical, but it may represent the early visceral component of a surgical process. Colicky pain is indicative of hollow viscus distention, and
Figure 21-1. Differential diagnosis of acute abdominal pain. CHF, congestive heart failure; GERD, gastroesophageal reflux disease; LLL, left lower lobe; RLL, right lower lobe.

**Figure 21-2.** Common locations of referred pain from abdominal etiology.

**Figure 21-3.** Common locations of referred pain from abdominal etiology. Perforated duodenal ulcer or ruptured spleen. Acute pancreatitis or renal colic. Biliary colic. Uterine or rectal pain.

**DIFFUSE PAIN**
- Peritonitis
- Pancreatitis
- Sickle cell crisis
- Early appendicitis
- Mesenteric thrombosis
- Gastroenteritis
- Dissecting or ruptured aneurysm
- Intestinal obstruction
- Diabetes mellitus
- Inflammatory bowel disease
- Irritable bowel

**RIGHT UPPER QUADRANT PAIN**
- Biliary colic
- Cholecystitis
- Gastritis
- GERD
- Hepatic abscess
- Acute hepatitis
- Hepatomegaly due to CHF
- Perforated ulcer
- Pancreatitis
- Retrocecal appendicitis
- Myocardial ischemia
- Appendicitis in pregnancy
- RLL pneumonia

**LEFT UPPER QUADRANT PAIN**
- Gastritis
- Pancreatitis
- GERD
- Splenic pathology
- Myocardial ischemia
- Pericarditis
- Myocarditis
- LLL pneumonia
- Pleural effusion

**RIGHT LOWER QUADRANT PAIN**
- Appendicitis
- Meckel’s diverticulitis
- Cecal diverticulitis
- Aortic aneurysm
- Ectopic pregnancy
- Ovarian cyst
- Pelvic inflammatory disease
- Endometriosis
- Ureteral calculi
- Psoas abscess
- Mesenteric adenitis
- Incarcerated/strangulated hernia
- Ovarian torsion
- Tubo-ovarian abscess
- Urinary tract infection

**LEFT LOWER QUADRANT PAIN**
- Aortic aneurysm
- Sigmoid diverticulitis
- Incarcerated/strangulated hernia
- Ectopic pregnancy
- Ovarian cyst
- Mittelschmerz
- Ovarian cyst
- Pelvic inflammatory disease
- Endometriosis
- Tubo-ovarian abscess
- Ureteral calculi
- Psoas abscess
- Urinary tract infection

The severity and descriptive nature of the pain are the most subjective aspects of the pain history, but a few classical descriptions are recognized, such as the following:

- The diffuse, severe, colicky pain of bowel obstruction
- The “pain out of proportion to examination” observed in patients with mesenteric ischemia
- The radiation of pain from the epigastrium straight through to the midback associated with pancreatitis, either related to primary organ inflammation or secondary to a penetrating ulcer
- The radiation of pain to the left shoulder or independent pain in the left shoulder associated with splenic pathology, diaphragmatic irritation, or free intraperitoneal fluid
- The onset of pain associated with syncope seen in perforation of gastric or duodenal ulcer, ruptured aortic aneurysm, or ruptured ectopic pregnancy

**Physical Examination**

The objective evaluation begins with measurement of the vital signs. Significant tachycardia and hypotension are indicators that hypovolemia or sepsis may be present. Tachypnea

<tr>
<th>CAUSE</th>
<th>EPIDEMIOLOGY</th>
<th>ETIOLOGY</th>
<th>PRESENTATION</th>
<th>PHYSICAL EXAMINATION</th>
<th>USEFUL TOOL(S)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ruptured ectopic pregnancy</td>
<td>Occurs in females of childbearing age. No method of contraception prevents ectopic pregnancy. Approximately 1 in every 100 pregnancies.</td>
<td>Risk factors include nonwhite race, older age, history of STD or PID, infertility treatment, intrauterine contraceptive device placed within the past year, tubal sterilization, and previous ectopic pregnancy.</td>
<td>Severe, sharp constant pain localized to the affected side. More diffuse abdominal pain with intraperitoneal hemorrhage. Signs of shock may be present. Midline pain tends not to be ectopic pregnancy.</td>
<td>Shock or evidence of peritonitis may be present. Lateralized abdominal tenderness. Localized adnexal tenderness or cervical motion tenderness increase the likelihood of ectopic pregnancy. Vaginal bleeding does not have to be present.</td>
<td>β-hCG testing necessary in all females of childbearing age (10–55 yr); combined with ultrasonography, preferably transvaginal in early pregnancy, usually is diagnostic. FAST exam is useful in evaluating for free fluid in patients with shock or peritonitis.</td>
</tr>
<tr>
<td>Ruptured or leaking abdominal aneurysm</td>
<td>Incidence increases with advancing age. More frequent in men. Risk factors include HTN, DM, smoking, COPD, and CAD.</td>
<td>Exact etiology is undetermined. Contributing factors include atherosclerosis, genetic predisposition, HTN, connective tissue disease, trauma, and infection.</td>
<td>Patient often asymptomatic until rupture. Acute epigastric and back pain often associated with or followed by syncope or signs of shock. Pain may radiate to back, groin, or testes.</td>
<td>Vital signs may be normal (in 70%) to severely hypotensive. Palpation of a pulsatile mass is usually possible in aneurysms 5 cm or greater. The physical examination may be nonspecific. Bruits or inequality of femoral pulses may be evident.</td>
<td>Abdominal plain films abnormal in 80% of cases. Ultrasound can define diameter and length but can be limited by obesity and bowel gas. FAST exam can be helpful in evaluating for leak by looking for free fluid. Spiral CT test of choice in stable patients.</td>
</tr>
<tr>
<td>Mesenteric ischemia</td>
<td>Occurs most commonly in elders with CV disease, CHF, cardiac dysrhythmias, DM, sepsis, and dehydration. Responsible for 1 of 1000 hospital admissions. Mortality 70%. Mesenteric venous thrombosis associated with hypercoagulable states, hematologic inflammation, and trauma.</td>
<td>20–30% of lesions are nonocclusive. The causes of ischemia are multifactorial, including transient hypotension in the presence of preexisting atherosclerotic lesion. The arterial occlusive causes (65%) are secondary to emboli (75%) or acute arterial thrombosis (25%).</td>
<td>Severe pain, colicky, that starts in periumbilical region and then becomes diffuse. Often associated with vomiting and diarrhea. Sometimes postprandial. “Mesenteric or abdominal angina.”</td>
<td>Early examination results can be remarkably benign in the presence of severe ischemia. Bowel sounds often still present. Rectal examination important because mild bleeding with positive guaiac stools can be present.</td>
<td>Often a pronounced leukocytosis is present. Elevations of amylase and creatine kinase levels are seen. Metabolic acidosis due to lactic acidemia is often seen with infarction. Plain radiographs of limited benefit. CT, MRI, and angiography are accurate to varying degrees.</td>
</tr>
<tr>

<td>--------------</td>
<td>----------------------</td>
</tr>
<tr>
<td>Intestinal obstruction</td>
<td>Peaks in infancy and older age. More common with history of previous abdominal surgery.</td>
<td>Adhesions, carcinoma, hernias, abscesses, volvulus, and infarction. Obstruction leads to vomiting, “third spacing” of fluid, or strangulation and necrosis of bowel.</td>
<td>Crampy diffuse abdominal pain associated with vomiting.</td>
<td>Vital signs usually normal unless dehydration or bowel strangulation has occurred. Abdominal distention, hyperactive bowel sounds, and diffuse tenderness. Local peritoneal signs indicate strangulation.</td>
<td>Elevated WBC count suggests strangulation. Electrolytes may be abnormal if associated with vomiting or prolonged symptoms. Abdominal radiographs and CT are useful in diagnosis.</td>
</tr>
<tr>
<td>Perforated viscus</td>
<td>Incidence increases with advancing age. History of peptic ulcer disease or diverticular disease common.</td>
<td>More often a duodenal ulcer that erodes through the serosa. Colonic diverticula, large bowel, and gallbladder perforations are rare. Spillage of bowel contents causes peritonitis.</td>
<td>Acute onset of epigastric pain is common. Vomiting in 50%. Fever may develop later. Pain may localize with omental walling off of peritonitis. Shock may be present with bleeding or sepsis.</td>
<td>Fever, usually of low grade, is common; worsens over time. Tachycardia is common. Abdominal examination reveals diffuse guarding and rebound. “Boardlike” abdomen in later stages. Bowel sounds are decreased.</td>
<td>WBC count usually elevated due to peritonitis. Amylase may be elevated; LFT results are variable. Upright radiographic view reveals free air in 70–80% of cases with perforated ulcers.</td>
</tr>
<tr>
<td>Acute pancreatitis</td>
<td>Peak age in adulthood; rare in children and elders. Male preponderance. Alcohol abuse and biliary tract disease are risk factors.</td>
<td>Alcohol, gallstones, hyperlipidemia, hypercalcemia, or endoscopic retrograde pancreatography causing pancreatic damage, saponification, and necrosis. ARDS, sepsis, hemorrhage, and renal failure are secondary.</td>
<td>Acute onset of epigastric pain radiating to the back. Nausea and vomiting are common. Pain disproportionate to physical findings. Adequate volume repletion is important in the initial therapy.</td>
<td>Low-grade fever common. Patient may be hypotensive or tachypneic. Some epigastric tenderness usually present. Because pancreas is retroperitoneal organ, guarding or rebound not present unless condition is severe. Flank ecchymosis or periumbilical ecchymosis may be seen if process is hemorrhagic.</td>
<td>Lipase determination is test of choice. Ultrasound exam may show edema, pseudocyst, or biliary tract disease. CT scan may show abscesses, necrosis, hemorrhage, or pseudocysts. CT is ordered if severe acute pancreatitis is suspected. Rule out gallstones with ultrasound exam.</td>
</tr>

BOX 21-2 HIGH-YIELD HISTORICAL QUESTIONS

1. How old are you? Advanced age means increased risk.
2. Which came first—pain or vomiting? Pain first is worse (i.e., more likely to be caused by surgical disease).
3. How long have you had the pain? Pain for less than 48 hours is worse.
5. Is the pain constant or intermittent? Constant pain is worse.
6. Have you ever had this before? A report of no prior episodes is worse.
7. Do you have a history of cancer, diverticulosis, pancreatitis, kidney failure, gallstones, or inflammatory bowel disease? All are suggestive of more serious disease.
8. Do you have human immunodeficiency virus (HIV)? Consider occult infection or drug-related pancreatitis.
9. How much alcohol do you drink per day? Consider pancreatitis, hepatitis, or cirrhosis in patients with history or signs of significant intake.
10. Are you pregnant? Test for pregnancy—consider ectopic pregnancy.
11. Are you taking antibiotics or steroids? Effects of these drugs may mask infection.
12. Did the pain start centrally and migrate to the right lower quadrant? High specificity for appendicitis.
13. Do you have a history of vascular or heart disease, hypertension, or atrial fibrillation? Consider mesenteric ischemia and abdominal aneurysm.

Figure 21-3. The characteristics of colicky abdominal pain.

may be an indication of metabolic acidosis from gangrenous visceras or sepsis, hypoxemia from pneumonia, or simply a catecholamine-induced reaction to pain. Elevated temperature often is associated with intra-abdominal infections. Although important, vital signs may be misleading and should be inter-

preted in the context of the entire presentation. Tachycardia may develop late for various reasons in hypovolemic. Temperature often is normal in elderly patients with laparotomy-proven intra-abdominal infections. Septic elderly patients also may present with hypothermia.

A thorough abdominal examination is an essential part of the evaluation of the patient with abdominal pain. This requires properly positioning the patient supine and exposing the abdomen. The examination should begin with inspection for any signs of trauma, bruising, or skin lesions. The patient should be asked to localize the area of maximal tenderness by pointing with one finger. The abdomen can be mentally divided into four quadrants: right upper, right lower, left upper, and left lower; each area is then examined individually. Tenderness in one quadrant often corresponds with the location of the diseased organ, which will direct the workup (see Fig. 21-1). Some disease processes may manifest with pain that is not exclusively within one specific quadrant, such as the suprapubic pain of a urinary tract infection or the midepigastric pain of a gastric ulcer. Although 80% of patients with suspected appendicitis present with right lower quadrant abdominal tenderness, 20% of patients with proven appendicitis do not.

Rectal examination may have limited use in the evaluation of abdominal pain, except that associated with intraluminal gastrointestinal hemorrhage, prostatitis, or perirectal disease. The main utility of the rectal examination is in the detection of heme-positive stool, anal fissures or fistulas, or stool impaction. Rectal examination has not been shown to increase diagnostic accuracy for appendicitis when added to external physical examination of the abdomen.

The abdominal examination should include a pelvic examination in female patients with lower abdominal pain or an otherwise uncertain diagnosis. The pelvic exam should be done early in the evaluation of the female patient with abdominal pain to help differentiate an abdominal from a pelvic source. This information is helpful in choosing an imaging modality. Pelvic ultrasound exam is helpful in evaluating uterine and ovarian pathology, whereas computed tomography (CT) is more beneficial in evaluation of suspected intra-abdominal pathology. Although the pelvic exam may guide the initial choice of imaging modality, overlap in exam findings is common. For example a patient with right lower quadrant tenderness may have both right adnexal tenderness and tenderness over McBurney’s point—necessitating exclusion of both appendicitis and ovarian torsion. The diagnosis highest on the differential list should be ruled out first using the corresponding imaging modality.

In the male patient with abdominal pain, the urogenital system should be examined. Diseases such as prostatitis, orchitis, and epididymitis commonly cause abdominal pain in males. Furthermore, inguinal hernias are more common in males, with the possibility of strangulation or incarceration in the inguinal canal making a thorough genitourinary examination mandatory.

In view of the evolving nature of abdominal pain, repetitive examinations may be useful. This is common practice with respect to suspected appendicitis and has improved the diagnostic accuracy in patients whose presentations were atypical.

Ancillary Testing

Urinalysis and testing for pregnancy are perhaps the most time- and cost-effective adjunctive laboratory tests available. Results often can be obtained quickly, so the former can lead to an early diagnosis and the latter may significantly affect
further evaluation and management approaches. It is necessary to interpret urinalysis results within the context of the patient’s clinical picture. Pyuria, with or without bacteriuria, often is present in a variety of conditions besides a simple urinary tract infection. For example, appendicitis may feature sterile pyuria. Similar to hematuria, pyuria usually is present with the relatively benign condition of nephrolithiasis but may also indicate an abdominal aortic aneurysm.

Complete blood counts frequently are ordered for patients with abdominal pain, but findings seldom are contributory to a diagnosis. Despite the association of elevated white blood cell (WBC) counts with many infectious and inflammatory processes, the WBC count is neither sufficiently sensitive nor specific to be considered a discriminatory test to help establish or rule out a serious cause for the pain. Even serial WBC counts have failed to differentiate surgical from nonsurgical conditions. The WBC count is therefore not helpful for diagnosis. Serum electrolytes, even in the presence of protracted emesis or diarrhea, are abnormal in less than 1% of patients. These studies are not indicated for most patients in the absence of another indication. Blood urea nitrogen concentrations can be elevated in gastrointestinal hemorrhage and dehydration, but such conditions are better detected and quantified by history and physical examination. Increased serum creatinine usually is indicative of renal dysfunction. Blood glucose, anion gap, and serum ketone determinations are useful in diabetic ketoacidosis, one cause of acute abdominal pain and tachypnea.

Liver enzymes and coagulation studies are helpful only in a small subset of patients with suspected liver disease. If pancreatitis is suspected, the most useful diagnostic result is serum lipase elevated to at least double the normal value, because it is more specific and more sensitive than serum amylase for this process. Measurement of serum amylase is of no value if a serum lipase level is available. Serum phosphate and serum lactate levels are elevated late in bowel ischemia, and such determinations may be useful if this entity is suspected but cannot be considered either sufficiently sensitive or specific to establish or exclude the diagnosis on their own.

Plain radiography of the abdomen has limited usefulness in the evaluation of acute abdominal pain. Suspected bowel obstruction, foreign body, and perforated viscus are the main indications. CT of the abdomen has become the imaging modality of choice with nonobstetric abdominal pain. It allows visualization of both intraperitoneal and extraperitoneal structures and has a high degree of accuracy, establishing a diagnosis in more than 95% of cases in one study and increasing the confidence in diagnosis in another. Incidental findings are common on CT scans and may lead to a diagnosis. Patients who undergo CT have a change in diagnosis more often than those who do not. The proper execution and interpretation of CT studies will reduce morbidity, mortality, and medical expenses.

CT has increased diagnostic utility in elderly patients for several reasons. Older people with abdominal pain may have twice the rate of surgery and a six- to eight-fold increase in mortality compared with younger adults. Furthermore, evaluation of abdominal pain in the elderly often is more challenging owing to unreliable findings on physical examination including vital signs, difficulties in history taking, physiologic age-related changes, and comorbid conditions. In the elderly population, CT results change management or disposition decisions in a significant proportion of patients. Table 21-3 lists the most common findings on CT scans in elderly patients with abdominal pain.

Some controversy surrounds the use of oral contrast in abdominal CT in the critically ill ED patient. Technologic advances have improved image acquisition and resolution, and preliminary studies have shown that intravenous contrast alone may now be adequate in the evaluation of certain suspected pathologic processes, such as solid organ or bowel wall disease. CT with intravenous contrast alone also has been shown to be sensitive and specific for the confirmation or exclusion of acute appendicitis. The exclusion of oral contrast in these patients significantly decreases ED time to disposition and improves patient satisfaction.

Bedside transabdominal and transvaginal ultrasonography have emerged as extremely useful adjuncts, decreasing time to diagnosis of life-threatening abdominopelvic conditions. Useful indications include the following:

- Identification of an intrauterine pregnancy, effectively lowering the chances of an ectopic pregnancy to less than 1 in 20,000 (In women using fertility aids, however, identification of intrauterine pregnancy does not exclude ectopic pregnancy, in keeping with an increased incidence of heterotopic pregnancy.)
- Measurement of the cross-sectional diameter of the abdominal aorta to determine whether an abdominal aortic aneurysm exists
- Detection of free intraperitoneal fluid indicating hemorrhage, pus, or extrusion of gut contents
- Use as a diagnostic aid for detection of the following non–life-threatening conditions:
  - Gallstones or a dilated common bile duct, which may be a clue to the presence of choledocholithiasis
  - Pericholecystic fluid or gallbladder wall thickening, which may be indicative of cholecystitis
  - Free intraperitoneal fluid indicating ascites
  - Hydroureter indicating possible obstructive uropathy
  - Inferior vena cava distention or collapse as an indicator of volume status

The results of sonographic examinations are operator-dependent, and misdiagnosis can occur because of failure to detect or identify pathology, incorrect identification of normal anatomy as pathologic, or overinterpretation of correctly identified findings (e.g., the mere presence of gallstones does not indicate that cholelithiasis is the cause of the pain). The emergency physician must be properly trained in image acquisition and interpretation, and ultrasound evaluation in the radiology department should be sought if there is ambiguity or uncertainty in findings.

**DIFFERENTIAL DIAGNOSIS**

The differential considerations with abdominal pain include a significant number of potentially life- or organ-threatening entities, particularly in the setting of a hemodynamically unstable or toxic-appearing patient. Severely ill patients require timely resuscitation and expeditious evaluation for potentially life-threatening conditions. A focused history and exam should be performed, and the patient should be placed in a monitored acute care area well equipped for airway control, quick intravenous access, and fluid administration. Only then should appropriate diagnostics be initiated (bedside focused assessment with sonography in trauma [FAST] and aorta ultrasound assessment and radiographic, electrocardiographic, and laboratory studies). This approach is particularly important in dealing with elderly or potentially pregnant patients (see Tables 21-1 and 21-2).

Women of reproductive age who present with abdominal pain should undergo pregnancy testing early, and a known pregnancy or a positive result on urine or serum pregnancy testing associated with abdominal pain in the ED should be considered to represent an ectopic pregnancy until proved otherwise. If evidence of blood loss is present, early obstetric consultation and diagnostic ultrasonography should be promptly sought. Bedside transabdominal sonography may identify free intraperitoneal fluid during the evaluation of shock, which may be sufficient evidence to justify operative intervention in the context of a positive pregnancy test and appropriate history and physical findings.

Despite the limitations already described, the approach to the differential diagnosis of abdominal pain generally is based on the location of maximum tenderness. Figure 21-1 shows locations of subjective pain and maximal tenderness on palpation related to various underlying causes. In women of childbearing age, a positive result on pregnancy testing may indicate ectopic pregnancy, but the entire spectrum of intra-abdominal conditions remains in the differential diagnosis, as for the non-pregnant patient. When the very broad differential list is compartmentalized by both history and physical examination, ancillary testing should proceed to either confirm or support the clinical suspicion.

Despite the significant variety of tests available, close to one half of the patients presenting to the ED with acute abdominal pain will have no conclusive diagnosis. It is incumbent on the clinician to reconsider the extra-abdominal causes of abdominal pain (see Box 21-1), with special consideration in elderly and immunocompromised patients, before arriving at the diagnosis of “nonspecific abdominal pain.”

**EMPIRICAL MANAGEMENT**

The main therapeutic goals in managing acute abdominal pain are physiologic stabilization, mitigation of symptoms (e.g., emesis control, pain relief), and expeditious diagnosis, with consultation, if required.

There is no evidence to support withholding analgesics from patients with acute abdominal pain to preserve the accuracy of subsequent abdominal exams; in fact, the preponderance of evidence supports the opposite. Pain relief may facilitate the diagnosis in patients ultimately requiring surgery. 26-28 In the acute setting, analgesia usually is accomplished with intravenously titrated opioids. Meperidine (Demerol) has an unfavorable side effect profile and should be avoided. Intravenous ketorolac, the only parenteral nonsteroidal anti-inflammatory drug available in North America, is useful for both ureteral and biliary colic, 29,30 as well as some gynecologic conditions, but is not indicated for general treatment of undifferentiated abdominal pain. Among patients with gastrointestinal hemorrhage and potential surgical candidates, ketorolac has been shown to increase bleeding times in healthy volunteers. 31

Aside from analgesics, a variety of other medications may be helpful to patients with abdominal pain. The burning pain caused by gastric acid may be relieved by antacids. 32 Intestinal cramping may be diminished with oral anticholinergics such as the combination agent atropine-scopolamine-hyoscyamine-phenobarbital (Donnatal), although evidence for this is scant and highly variable.

Antiemetics such as promethazine, prochlorperazine, ondansetron, granisetron, or inapsine can be useful for nausea and vomiting. Gastric emptying by nasogastric tube with suction is appropriate for suspected small bowel obstruction and intractable pain or vomiting.

If intra-abdominal infection is suspected, broad-spectrum antibiotic therapy should be initiated promptly. Abdominal infections are often polymicrobial and coverage for enteric gram-negative, gram-positive, and anaerobic bacteria must be included. In the choice of antibiotic or combination, the following should be considered:

- Unless local antibiotic resistance surveillance indicates otherwise, second-generation cephalosporins (e.g., cefamandole, cefotetan, cefoxitin) or quinolone (ciprofloxacin, levofloxacin) may be combined with metronidazole for the initial dose of antibiotics in the ED. Other noncephalosporin, β-lactam agents with β-lactamase antagonists (e.g., ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanate) are alternatives.
- Many enteric gram-negative bacilli mutate rapidly to produce β-lactamases that are poorly antagonized by specific drug combinations containing clavulanate, sulbactam, or tazobactam. A carbapenem (e.g., imipenem, meropenem) or ceftazime is an alternative for patients who may have recently received other antibiotics. 30,33

Whether to provide coverage for *Enterococcus* species is still a subject of debate, and the decision to treat for these bacteria specifically can be made after consultation. Immunocompromised patients may require antifungal agents.

**DISPOSITION**

Because up to 40% of patients presenting with acute abdominal pain receive the diagnosis of nonspecific abdominal pain, the disposition can be as difficult as the diagnosis in these patients. Categories for disposition may include surgical versus nonsurgical consultation and management, admission for observation, and discharge to home with follow-up evaluation. 34 The decision to admit a patient to an observation unit or a hospital bed must factor in the following:
Information gained from the history, physical examination, and test results
- The likelihood of any suspected disease
- Any potential ramifications of progression of a known disease, or of incorrect diagnosis or management
- The likelihood of appropriate (or any) and timely follow-up after hospital discharge

Clinically stable patients may be discharged from the ED with appropriate follow-up care, possibly to include repeated physical exam or additional diagnostic imaging if indicated. In the case of nonspecific abdominal pain that is considered potentially worrisome, it is prudent to have the patient reevaluated after 8 to 12 hours. This can be done through a return visit to the ED, an appointment with a primary care physician, or an observation unit protocol.

Before discharge of a patient with an undiagnosed cause of nonspecific abdominal pain, several conditions should be met: The abdominal examination findings should be benign overall, with normal vital signs. Pain and nausea should be controlled, and the patient should be able to eat and drink. If a patient is to be discharged home without a specific diagnosis, clear instructions to the patient must include the following information:

- What the patient has to do for relief of symptoms or to maximize chances of resolution of the condition (e.g., avoiding exacerbating food or activities, taking medications as prescribed)
- Under what circumstances, with whom, and in what time frame to seek follow-up evaluation, if all goes as desired on the basis of what is known when the patient is in the ED
- Under what conditions the patient should seek more urgent care because of unexpected changes in his or her condition (such as with natural progression of the process before improvement, incorrect diagnosis made in the ED, or untoward reactions to medications)

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Gastrointestinal (GI) bleeding is a relatively common problem encountered in emergency medicine that often requires early consultation and hospital admission. The overall mortality rate for GI bleeding is approximately 10% and has not changed significantly since the 1960s. Diagnostic modalities have improved much more than therapeutic techniques. GI bleeding is often easy to identify when there is clear evidence of vomiting blood or passing blood in the stool, but the clinical presentation may be subtle, with signs and symptoms of hypovolemia, such as dizziness, weakness, or syncope.

The approach to GI bleeding depends on whether the hemorrhage is located in the proximal or the distal segment of the GI tract (i.e., upper or lower GI bleeding). These segments are anatomically defined by the ligament of Treitz in the fourth section of the duodenum. In the United States, upper GI bleeding (UGIB) affects 50 to 150 people per 100,000 population each year and results in more than 300,000 admissions and about 30,000 deaths per year at an estimated annual cost of almost $1 billion. Lower GI bleeding (LGIB) affects a smaller portion of patients and results in proportionally fewer hospital admissions than UGIB.1

GI bleeding can occur in persons of any age but most commonly affects people in their 40s through 70s (mean age, 59 years). Most deaths caused by GI bleeding occur in patients older than 60 years. UGIB is more common in men than in women (in a 2:1 ratio), whereas LGIB is more common in women. Significant UGIB requiring admission is more common in adults, whereas LGIB requiring admission is more common in children.2

DIAGNOSTIC APPROACH

Differential Considerations

Peptic ulcer disease, gastric erosions, and varices account for approximately three fourths of adult patients with UGIB (Box 22-1). Diverticulosis and angiodysplasia account for approximately 80% of adults with LGIB. In children, esophagitis, gastritis, and peptic ulcer disease are the most common causes of UGIB, and infectious colitis and inflammatory bowel disease are the most common causes of LGIB (Box 22-2). In children younger than 2 years of age, massive LGIB is most often a result of Meckel’s diverticulum or intussusception. At all ages, anorectal abnormalities are the most common cause of minor LGIB. Despite improved diagnostic techniques, no source of bleeding is identified in approximately 10% of patients with GI bleeding. In patients with abdominal aortic grafts who present to the emergency department (ED) with GI bleeding, the possibility of aortoenteric fistula should be considered. Prompt surgical consultation in the ED should be obtained if this is suspected, because bleeding can be massive and fatal.

Rapid Assessment and Stabilization

Most patients with GI bleeding are easy to diagnose because they present to the ED complaining of vomiting blood or passing black or bloody stool. The diagnosis is confirmed quickly by examination of the stool for the presence of blood.

Patients with suspected GI bleeding who are hemodynamically unstable should undergo rapid evaluation and resuscitation. They should be undressed quickly to permit placement of cardiac and oxygen saturation monitors, and supplemental oxygen should be given as needed. At least two large-bore peripheral intravenous lines should be placed (minimum 18-gauge); blood should be drawn for hemoglobin or hematocrit, platelet count, prothrombin time (PT), and type and screen or type and crossmatch studies; and crystalloid resuscitation should be initiated. Intravenous crystalloid fluid should be given as a 2-L bolus in adults or 20 mL/kg in children until the patient’s vital signs have stabilized or the patient has received 40 mL/kg of crystalloid in an adult or 60 mL/kg as a child. Patients who remain unstable after 40 to 60 mL/kg of crystalloid should be given type O, type-specific, or crossmatched blood, depending on availability. Persistently unstable patients should receive immediate consultation with a gastroenterologist for UGIB and with a surgeon for LGIB.3

Pivotal Findings

History, physical examination, testing a stool sample for blood, and measuring hemoglobin or hematocrit are the keys to diagnosing GI bleeding in most patients.

History

Patients typically complain of vomiting red blood or coffee grounds–like material, or passing black or bloody stool. Hematemesis (vomiting blood) occurs with bleeding of the esophagus, stomach, or proximal small bowel. Approximately

50% of patients with UGIB present with this complaint. Hematemesis may be bright red or darker (i.e., coffee grounds–like) as a result of the conversion of hemoglobin to hematin or other pigments by hydrochloric acid in the stomach. The color of vomited or aspirated blood from the stomach does not differentiate between arterial and venous bleeding.

Melena, or black tarry stool, will result from the presence of approximately 150 to 200 mL of blood in the GI tract for a prolonged period. Melena is seen in approximately 70% of patients with UGIB and in one third of patients with LGIB. Black stool that is not tarlike may result from presence of 60 mL of blood from the upper GI tract. Blood from the duodenum or jejunum must remain in the GI tract for approximately 8 hours before turning black. Occasionally, black stool may follow bleeding into the lower portion of the small bowel and ascending colon. Stool may remain black and tarry for several days, even though bleeding has stopped. Black stool also may be seen after ingestion of bismuth (e.g., Pepto-Bismol), which can confuse the situation because such preparations are often taken for UGI distress. In contrast with melena, stool rendered black by bismuth is not positive on Hemoccult testing.

Hematochezia, or bloody stool (bright red or maroon), most often signifies LGIB but may be due to a brisk UGIB with rapid transit time through the bowel in 10 to 15% of patients. Because UGIB is much more common than LGIB, a more proximal source of significant bleeding must be excluded before assuming the bleeding is from the lower GI tract. Approximately two thirds of patients with LGIB present with red blood from bleeding per rectum. Small amounts of red blood (e.g., 5 mL) from rectal bleeding, such as bleeding due to hemorrhoids, may cause the water in the toilet bowl to appear bright red. Bright red stools also can be seen after ingestion of a large quantity of beets; in this case, Hemoccult testing would be negative and the patient also will report pink-colored water in the toilet bowl.

In taking the history, specific questions should address the duration and quantity of bleeding, associated symptoms, previous history of bleeding, current medications, alcohol, nonsteroidal anti-inflammatory drug use and long-term aspirin ingestion, allergies, associated medical illnesses, previous surgery, treatment by nonhospital personnel, and the response to that treatment. Patients with GI bleeding may report symptoms of hypovolemia, such as dizziness, weakness, or loss of consciousness, most often after standing up. Other nonspecific complaints include dyspnea, confusion, and abdominal pain. Rarely an elderly patient may present with ischemic chest pain precipitated by significant anemia due to a GI bleed. One in five patients with GI bleeding may have only nonspecific complaints.

The history is of limited help in predicting the site or quantity of bleeding. Patients with a previously documented GI lesion bleed from the same site in only 60% of cases. Gross estimates of blood loss based on the volume and color of the vomitus or stool (e.g., brown or black, pink or red) or the number of episodes of hemorrhage are notoriously inaccurate.

Physical Examination

**Vital Signs** Vital signs and postural changes in heart rate and blood pressure have been used to assess the amount of blood loss in patients with GI bleeding but are insensitive and nonspecific, with the exception of significant, sustained heart rate increase and hypotension. All patients with a history suggesting GI bleeding who are hypotensive, are tachycardic, or experience sustained posture-induced changes in heart rate of greater than 20 beats per minute should be assumed to have a significant hemorrhage. Normal vital signs do not exclude a significant hemorrhage, and postural changes in heart rate and blood pressure may occur in individuals who are not bleeding (e.g., elderly patients, many normal individuals, individuals on certain medications such as beta-blockers, individuals with hypovolemia from other causes).

**General Examination** The physical examination is valuable in establishing a specific diagnosis and assessing the severity of blood loss and the physiologic response to that loss. Careful attention is given to the patient’s general appearance, vital signs, mental status (including restlessness), skin signs (e.g., color, warmth, and moisture to assess for shock, or presence of lesions such as telangiectasia, bruises, or petechiae to assess for vascular diseases or hypocoagulable states), pulmonary and cardiac findings, abdominal examination, and rectal and stool examination. Frequent reassessment is important because a patient’s status may change quickly.

**Rectal Examination** Rectal and stool examinations are often key to making or confirming the diagnosis of GI bleeding. The finding of red, black, or melanic stool early in the assessment is helpful in prompting early recognition and management of patients with GI bleeding. The absence of black or bloody stool, however, does not exclude the diagnosis of GI bleeding. Regardless of the apparent character and color of the stool, occult blood testing is indicated.

Ancillary Testing

**Tests for Occult Blood** The presence of hemoglobin in occult amounts in stool is confirmed by tests such as guaiac assays (e.g., Hemoccult, HemaPrompt). Stool tests for occult blood may have positive results 14 days after a single, major episode of UGIB. False-positive results have been associated with the ingestion of certain fruits (e.g., cantaloupe, grapefruit, figs), uncooked vegetables (e.g., radish, cauliflower, broccoli) and red meat, methylene blue, chlorophyll, iodide, cupric sulfate, and bromide preparations. False-negative results are uncommon but can be caused by bile or ingestion of magnesium-containing antacids or aspiric acid. Tests to evaluate gastric contents for occult blood (e.g., Gastro occult) can be unreliable.
and should not be used for this purpose. In newborns, maternal blood that is swallowed may cause bloody stools; the Apt test may show that it is maternal in origin.

**Clinical Laboratory Tests** Blood should be drawn for evaluation of baseline hematocrit or hemoglobin, coagulation studies (PT and platelet count), and type and crossmatch studies (or type and screen studies if the patient is stable). The initial hematocrit may be misleading in patients with preexisting anemia or polycythemia. Changes in the hematocrit may lag significantly behind actual blood loss. Infusion of normal saline speeds equilibration of the hematocrit; however, rapid infusion of crystalloid in nonbleeding patients also may cause a decrease in hematocrit by hemodilution. The optimal hematocrit with respect to oxygen-carrying capacity and viscosity in critically ill patients has been reported to be 33%. In general, patients with a hemoglobin concentration of 8 g/dL or less (hematocrit <25%) from acute blood loss usually require blood therapy. After transfusion and in the absence of ongoing blood loss, the hematocrit can be expected to increase approximately 3% for each unit of blood administered (hemoglobin level increases by 1 mg/dL).

The PT should be used to determine whether a patient has a preexisting coagulopathy. An elevated PT may indicate vitamin K deficiency, liver dysfunction, warfarin therapy, or consumptive coagulopathy. Patients receiving therapeutic anticoagulants or patients with an elevated PT and evidence of active bleeding should receive sufficient fresh frozen plasma to correct the PT. Serial platelet counts are used to determine the need for platelet transfusions (i.e., less than 50,000/mm³).

**Blood Bank** Blood should be sent for “type and hold” or type and crossmatch studies early in the patient’s care. Immediate transfusion needs in unstable patients can be met with O-positive packed red blood cells (O-negative packed red blood cells in women of childbearing age whose Rh status is unknown). Type-specific blood is usually available within 10 to 15 minutes. Group O blood and type-specific blood are safe for patients and cause few transfusion reactions. Fully crossmatched blood may take 60 minutes to prepare. Stable patients can be managed more cost-effectively by ordering “type and hold” without crossmatching for units of blood.

**Other Laboratory Tests** Electrolytes usually are normal in patients with GI bleeding. However, determination of electrolytes, blood urea nitrogen, and creatinine may be useful in a small percentage of patients with GI bleeding when indicated. For example, in patients with repeated vomiting, hypokalemia, hypernatremia, and metabolic alkalosis may develop, which usually correct with adequate hydration and the resolution of vomiting. Patients with shock often have metabolic acidosis from lactate accumulation. The blood urea nitrogen is elevated in many patients with UGIB as a result of the absorption of blood from the GI tract and hypovolemia causing prerenal azotemia. After 24 hours, hypovolemia probably is the sole determinant of azotemia unless there has been recurrent bleeding or there is baseline renal insufficiency.

**Electrocardiogram** An electrocardiogram (ECG) should be obtained in all patients with a GI bleed who are older than 50 years of age or have preexisting ischemic cardiac disease, significant anemia, or chest pain, shortness of breath, or persistent hypotension. Asymptomatic myocardial ischemia (ST segment depression greater than 1 mm) or injury (ST segment elevation greater than 1 mm) may develop in the setting of GI bleeding. Patients with GI bleeding and clinical or ECG evidence of myocardial ischemia should receive packed red blood cells as soon as possible, as well as appropriate treatment for myocardial ischemia.

**Imaging** GI hemorrhage is not an indication for plain abdominal radiography. An upright chest radiograph should be obtained in patients with UGIB suspected of aspiration or with signs and symptoms of bowel perforation (shock with significant abdominal or peritoneal tenderness). Subdiaphragmatic air consistent with bowel perforation is a rare finding with UGIB, but it is an indication for immediate surgical consultation and operative repair.

**DIFFERENTIAL DIAGNOSIS**

Not all patients complaining of vomiting blood or passing blood in the stool have GI bleeding. Swallowing blood during epistaxis or from the oral cavity may cause hematemesis or melena. Red vomitus may be due to food products (e.g., Jell-O, tomato sauce, wine), and black stool may be due to iron therapy or bismuth (e.g., Pepto-Bismol). Hypovolemia (and its symptoms) may be due to vomiting and diarrhea without bleeding. Poor oral intake with or without fever also may result in hypovolemia. Usually the patient’s hemoglobin or hematocrit is normal or elevated until hemodilution can occur. There are many causes of anemia other than GI bleeding. In the absence of suggestive symptoms or blood in the stool, GI bleeding is less likely to be the cause of observed anemia.

**MANAGEMENT**

Quick identification, aggressive resuscitation, risk stratification, and prompt consultation are the keys to appropriate emergency management. When the diagnosis of GI bleeding is made, emergency management of patients can proceed (Fig. 22-1).

**Reassurance**

Patients who present to the ED with symptoms and signs of GI bleeding are often frightened by their symptoms. They may be concerned about the possibility of painful procedures and of the real or perceived risk of death. These patients and their families should be treated in a supportive and reassuring manner. They should be provided with accurate information about their problem, and all aspects of the care they are receiving should be explained in a way that they understand.

**Nasogastric Tube and Gastric Lavage**

After initial resuscitation of the patient, it is important to identify whether the hemorrhage is proximal or distal to the ligament of Treitz (i.e., UGIB or LGIB). If the patient’s vomitus demonstrates blood, then the diagnosis of UGIB is confirmed. If a patient reports bloody or “coffee grounds” emesis or if melena stool is present, an upper GI bleed is more likely. Placement of a nasogastric (NG) tube formerly was widely undertaken in the belief that it had both diagnostic and therapeutic benefit. Although in some cases, an NG tube may help to establish or confirm the diagnosis of UGIB, it is not useful for risk stratification. Aspiration of bloody contents from the NG tube diagnoses UGIB (or bleeding from nasal or oral passageways), but it does not determine if the bleeding is ongoing or has already stopped. Earlier assertions that gastric lavage “until clear” demonstrated that the bleeding had stopped have been refuted by findings at endoscopy. There is a 10% incidence of failure to aspirate blood through the NG tube in established UGIB. False-negative results are possible if the bleeding is intermittent or has already stopped and the stomach is cleared, or if the bleeding is in the duodenum, and edema or spasm of the pylorus has prevented reflux of
Gastric tubes are safe in most patients, but pharyngeal and esophageal perforation, cardiac arrest, ethmoid sinus fracture with brain trauma, and bronchial intubation have been reported. No evidence exists that gastric tube placement aggravates hemorrhage from varices or Mallory-Weiss tears. Gastric lavage may be helpful to prepare a patient for endoscopy. Before gastric lavage, patients with evidence of a possible perforated viscus (e.g., severe pain, peritoneal signs) should undergo radiologic assessment looking for free air. Lavage should not be performed in the presence of pneumoperitoneum. Gastric lavage does not reduce blood loss in patients with UGIB, and use of iced lavage fluid is not recommended. Gastric lavage in preparation for endoscopy is best performed with a large-bore Ewald tube, passed orally while the patient is in the left lateral decubitus position with the bed in Trendelenburg position. Additional holes may be cut in the distal portion of the Ewald tube to improve aspiration of blood and clots. Clots that cannot be aspirated continue to cause pink return, giving the false impression of continued bleeding. The irrigant need not be sterile; regular tap water may be used. The irrigant should be delivered and removed by gravity in volumes of 200 to 300 mL until the return is clear. Little irrigant is absorbed by the patient. Gastric rupture has been reported as a rare complication of gastric lavage. Anoscopy/Proctosigmoidoscopy

Patients with mild rectal bleeding who do not have obviously bleeding hemorrhoids should undergo anoscopy or proctosigmoidoscopy. If bleeding internal hemorrhoids are discovered, and the patient does not have portal hypertension, the patient may be discharged with appropriate treatment and follow-up evaluation for hemorrhoids. If hemorrhoids are not detected, it is important to determine if the stool above the rectum contains blood. The absence of blood above the rectum in a patient who is actively bleeding indicates that the source of bleeding is in the rectum. The presence of blood above the anoscope or sigmoidoscope does not invariably indicate a proximal source of bleeding, because retrograde passage of blood into the more proximal colon commonly occurs. Such patients need further evaluation.

Endoscopy

Endoscopy is the most accurate diagnostic tool available for the evaluation of UGIB. It identifies a lesion in 78% to 95% of patients with UGIB if it is performed within 12 to 24 hours of the hemorrhage. Accurate identification of the bleeding site allows for risk stratification with respect to predicting rebleeding and mortality. Endoscopy-based triage significantly reduces hospitalization rates and costs of treating upper GI bleeding. Significant advances in endoscopic hemostasis also make it of therapeutic value in select patients (e.g., for banding or sclerosing of varices). Colonoscopy is an effective tool for diagnosis and selected treatment of LGIB.
Angiography and Tagged Red Blood Cell Scan

Angiography can detect the location of UGIB in two thirds of patients studied. Since the advent of endoscopy, however, the use of angiography has decreased significantly, and today angiography is used in only 1% of patients with UGIB. Angiography is used more commonly in patients with LGIB and usually in consultation with a general surgeon. Although angiography rarely diagnoses the cause of bleeding, it does identify the site of bleeding in approximately 40% of patients who have LGIB and in 65% of patients who eventually require surgical intervention. Angiography ideally is performed during active bleeding; this may be apparent from persistently unstable vital signs or continued transfusion requirements to establish or maintain an optimal hemoglobin or hematocrit level. Arterial embolization can be used in selected cases of LGIB.12 In some patients with more indolent or elusive bleeding, a nuclear isotope–tagged red blood cell scan, usually performed from the inpatient unit, may identify the bleeding site.

Gastric Acid Secretion Inhibition

All patients with peptic ulcer disease documented by endoscopy should receive therapy with a proton-pump inhibitor (e.g., omeprazole).13–15 There is no documented benefit to initiating this therapy or administering H2 antihistamines in the rebleeding occurrences.16,17 (See Chapter 87.) Octreotide may be considered, however, in an exsanguinating patient with probable variceal bleeding in whom endoscopy is not immediately available and vasopressin has not slowed the hemorrhage. Consultation with a surgeon or gastroenterologist is advisable.

Surgery

Surgery is indicated for all hemodynamically unstable patients with active bleeding who do not respond to appropriate intravascular volume replacement, correction of any coagulopathy, and endoscopic intervention (if available). The mortality rate for patients undergoing emergency procedures for GI bleeding is approximately 23%. Generally, surgery is indicated whenever the risk of ineffective medical therapy and continued hemorrhage outweighs that of surgical morbidity and mortality.19 Emergency surgical consultation should be considered when blood replacement exceeds 5 units within the first 4 to 6 hours or when 2 units of blood is needed every 4 hours (after replacement of initial losses) to maintain normal cardiac output.

**DISPOSITION**

**Risk Stratification**

Risk stratification involves combining historical, clinical, and laboratory data to determine the risk of death and rebleeding in patients presenting to an ED with GI bleeding. Patients can be sorted into four risk categories: very low, low, moderate, and high risk. Some patients present to the ED with a vague complaint of vomiting blood or passing blood from the rectum in whom detailed history and examination allows a diagnosis of hemorrhoid, or anal fissure, or there may be little or no objective evidence of significant GI bleeding. These patients can be categorized as very low risk and can be sent home without further diagnostic tests2,7,20 (Box 22-3).

Before discharge, patients should be educated about the signs and symptoms of significant GI bleeding and when to return to the ED or when to call their primary care physician. They should be given specific education about the possible or actual cause of the bleeding and specific treatment for that disorder. They should be educated about the side effects of any medications. Patients should undergo specific follow-up evaluation within 24 to 36 hours. They should be instructed to avoid aspirin, nonsteroidal anti-inflammatory drugs, and alcohol.21,22

Patients with low-risk, moderate-risk, and high-risk criteria are more complicated and require further assessment. Historically, nearly all patients with significant GI bleeding were admitted to the hospital. As health care has changed, a greater emphasis has been placed on outpatient management of select

---

**BOX 22-3**

**VERY-LOW-RISK CRITERIA FOR PATIENTS COMPLAINING OF GASTROINTESTINAL BLEEDING WHO CAN BE DISCHARGED HOME**

- No comorbid diseases
- Normal vital signs
- Normal or trace positive result on stool guaiac testing
- Negative findings on gastric aspiration, if done
- Normal or near-normal hemoglobin/hematocrit
- Good support systems
- Proper understanding of signs and symptoms of significant bleeding
- Immediate access to emergent care if needed
- Follow-up arranged within 24 hr
low-risk patients with GI bleeding. Studies have shown that combining clinical and endoscopic criteria provides an accurate estimation of the risk of rebleeding and mortality in patients with UGIB. These combined criteria have been used to identify patients with UGIB at low risk, who can be discharged home, and patients at moderate or high risk, who need to be admitted to an appropriate care site in the hospital. Risk stratification for patients with LGIB is less well studied, so nearly all patients with significant LGIB are admitted. Risk stratification can be used for patients with LGIB, however, to decide an appropriate inpatient care site.

Table 22-1 presents an initial risk stratification tool for patients with upper and lower GI bleeding. Combining clinical and endoscopic findings allows for final risk stratification, as shown in Table 22-2, to decide disposition, inpatient care site, and treatment. 

Patients with clinical evidence of GI bleeding should undergo endoscopy as soon as it is available for final risk stratification, inpatient triage, and determination of appropriate treatment (see Table 22-2). If endoscopy is not immediately available, patients with low clinical risk may be admitted to an ED observation unit or short-stay hospital bed until endoscopy can be performed. Patients with moderate clinical risk criteria may be admitted to an inpatient floor, intermediate care unit, or ICU, as indicated by specific patient management needs and depending on the capabilities of the institution. Patients with high clinical risk should be admitted to a closely monitored step-down unit or an ICU. The timing of endoscopy depends on availability, the acuity of the patient, the need for emergent therapy, the need to determine final care site, and the need to minimize length of stay.

Patients with LGIB that is not clearly due to hemorrhoids, fissure, or proctitis should be admitted to an inpatient bed. Patients with low risk may be admitted to an inpatient floor and prepared for a nuclear medicine imaging study (e.g., red blood cell–labeled study) or colonoscopy. Patients with high-risk criteria should be admitted to a step-down unit or ICU and considered for angiography to identify the site of LGIB. Patients with moderate-risk criteria require individualized determination of the most appropriate inpatient care site (floor, intermediate care bed, or ICU) and the most useful diagnostic studies (nuclear imaging or angiography).

Consultation with a surgeon should be obtained if it appears that more than 5 units of blood is required to achieve hemodynamic stability or if there is reasonable suspicion that operative intervention may be needed. This is especially true of patients older than 65 years of age. In general, the older the patient, the more aggressive the surgical management ought to be. Patients with a history of varices, persistent postural changes in heart rate, or significant bleeding of bright red blood per rectum are more likely to require surgery than are patients without these findings. Emergent vascular surgical consultation is needed for patients who have abdominal aortic grafts who present to the ED with GI bleeding, because of the possibility of an aortoenteric fistula.

* Patients with low-risk clinical and endoscopic findings can be discharged home with appropriate treatment based on diagnosis, scheduled follow-up evaluation within 24 hours, and proper patient education to ensure immediate return if signs of rebleeding appear.
† Patients may be discharged after 24 to 48 hours of in-hospital observation if there is no evidence of rebleeding, vital signs are normal, there is no need for further transfusion, and the hemoglobin or hematocrit has remained stable. They should be provided with appropriate treatment based on diagnosis, scheduled follow-up evaluation within 24 hours, and proper patient education to ensure immediate return if signs of rebleeding appear.
‡ Patients with high-risk clinical or endoscopic findings should be hospitalized and monitored closely for evidence of rebleeding.

Diarrhea

Robert E. Collier, John E. Gough, and Philip A. Clement

PERSPECTIVE

Diarrhea is a common presenting complaint in the emergency department (ED) and can account for up to 5% of all visits. Most cases of diarrhea are self-limited and require only supportive care. Conversely, patients with more serious infection and associated comorbidity may present with life-threatening dehydration and shock. There may be an associated sepsis and septic shock component. Numerous but relatively rare, noninfectious causes of diarrhea should also be considered.

Incidence

Worldwide, diarrhea remains a major health problem, accounting for approximately 4% of all deaths each year, which is estimated by the World Health Organization (WHO) to be 2.2 million victims (World Health Report, 2000). A large proportion of these deaths occur in small children in developing countries. Rotavirus causes 25% to 65% of childhood-associated diarrheal illnesses (3.5 million cases per year in the United States), whereas adults experience 74 million episodes of diarrhea annually. In the United States, 90% of diarrheal illnesses are caused by noroviruses (caliciviruses), of which more than 100 different strains are recognized. Patients at the extremes of age, those with significant comorbidity, those who are immunologically compromised, and those with iatrogenic illness are most vulnerable to significant morbidity and mortality. An estimated 60% of patients infected with human immunodeficiency virus (HIV) experience significant diarrhea during the course of their illness.

Most adults experience diarrhea many times during their lifetime. Diarrhea illnesses are the primary cause of many hospitalizations and hours of lost work.

Definition and Categorization

The term diarrhea is derived from the Greek words dia (“through”) and rhein (“to flow”). The two main categories of diarrhea-associated illness are infectious and noninfectious. Infectious causes represent about 85% of cases, whereas noninfectious causes account for only 15% of the total. Infectious diarrhea may be divided into viral, bacterial, and parasitic causes (Box 23-1), with estimates of their relative contributions being 70% for viral, 24% for bacterial, and 6% for parasitic infections.

Definitions for diarrhea have been proposed to standardize nomenclature, help the clinician determine a probable etiology, and direct empirical therapy if indicated:

- **Acute diarrhea** is defined as lasting for 14 days or less.
- **Persistent diarrhea** lasts for longer than 14 days.
- **Chronic diarrhea** lasts 30 days or longer.

Acute diarrhea presentations usually will be infectious. A majority of these cases are self-limited and caused by viral and bacterial pathogens. Persistent diarrhea suggests an enteric pathogen other than viral, such as bacterial or protozoa. Chronic diarrhea usually is associated with noninfectious causes and requires further testing to determine the etiology.

Normally, the small and large bowel absorb 99% of gastrointestinal tract secretions produced and liquids ingested each day. Any pathologic state that reduces water absorption by 1% can cause diarrhea. Diarrhea results from one or more of four different pathologic processes that are characteristic of the primary cause and that contribute to the decreased absorption of the gut.

**Secretary diarrhea** is caused by pathogens that produce cytotoxins that increase cellular permeability and cause the oversecretion of water and electrolytes. Most cases of diarrhea encountered in the ED are secretory. Noninfectious causes of secretory diarrhea include medications, toxic substances, endocrine disorders, and neoplasias (Box 23-2).

**Inflammatory diarrhea**, also described as invasive or severe diarrhea, or dysentery, results from cellular damage to the intestinal mucosa, leading to the hypersecretion of water, electrolytes, blood, mucus, and plasma proteins. This diarrhea most commonly is caused by invasive bacterial and parasitic pathogens that produce dysenteric illnesses (see Box 23-1). Some noninfectious causes of inflammatory diarrhea include chemotherapy, radiation therapy, hypersensitivity reactions, autoimmune disorders, ischemic colitis, and inflammatory bowel disease. With inflammatory diarrhea, fecal leukocytes and erythrocytes typically are present, as are systemic symptoms, and the diarrhea continues despite fasting.

**Osmotic diarrhea** occurs with the ingestion or malabsorption of osmotically active solutes. These solutes cause the osmotic movement of water into the intestinal lumen, which then overwhelms the gut’s ability to reabsorb it. Examples include the effects of osmotic laxatives and carbohydrate malabsorption. Steatorrhea results from osmotic effects of lipids not absorbed in malabsorption and maldigestion syndromes.

**Abnormal motility** generally is seen in patients with chronic diarrhea but is always a component of acute diarrhea. Hypomotility decreases contact time between luminal contents and the absorbing mucosa, limiting water and electrolyte absorption.
**Etiologic Agents of Infectious Diarrhea**

**Viral (60% of cases)**
- Astrovirus
- Calicivirus
- Coronavirus
- Cytomegalovirus*
- Enteric adenovirus
- Hepatitis A through G
- Herpes simplex virus
- HIV enteropathy
- Norwalk-like agents
- Norwalk virus
- Pararotavirus
- Picornavirus
- Rotavirus
- Small round viruses

**Bacterial (20% of cases)**

*Invasive*
- *Aeromonas* spp.
- *Campylobacter* spp.
- *Clostridium difficile*
- Enteroinvasive *E. coli*
- *Mycobacterium* spp.
- *Plesiomonas shigelloides*
- *Salmonella* spp.
- *Shigella* spp.
- *Vibrio fluvialis*
- *Vibrio parahaemolyticus*
- *Vibrio vulnificus*
- *Yersinia enterocolitica*
- *Yersinia pseudotuberculosis*

*Toxigenic*
- FOOD POISONING WITH PREFORMED TOXINS
  - *Bacillus cereus*
  - *Clostridium botulinum*
  - *Staphylococcus aureus*
  - TOXIN FORMATION AFTER COLONIZATION
  - *Aeromonas hydrophila*
  - *Clostridium perfringens*

**Parasitic (5% of cases)**
- *Protozoa*
  - *Balantidium coli*
  - *Blastocystis hominis*
  - *Cryptosporidium*
  - *Cyclospora*
  - *Dientamoeba fragilis*
  - *Entamoeba histolytica*
  - *Entamoeba polecki*
  - *Enteromonas hominis*
  - *Giardia lamblia*
  - *Isospora belli*
  - Microsporidia
  - *Sarcocystis hominis*

**Helminths**
- *Angiostrongylus costaricense*
- *Anisakiasis*
- *Ascaris lumbricoides*
- *Diphyllobothrium latum*
- *Enterobius vermicularis*
- Hookworms
- *Schistosoma* spp.
- *Strongyloides stercoralis*
- *Taenia* spp.
- *Trichinella spiralis*
- *Trichuris trichiura*

*Enterohemorrhagic* *E. coli* O157:H7
*Enterotoxigenic* *E. coli*
*Klebsiella pneumoniae*
*Shigella* spp.
*Vibrio cholerae*

**Other bacteria**

**Secondary Survey**

The physical examination should assess the patient’s overall health, toxicity, fever, volume status, signs of a surgical abdomen, and determine the presence of blood in the stool. Young healthy adults may maintain a normal blood pressure and heart rate even with significant dehydration. In patients who are taking antiarrhythmic or beta-blocker medications or have conductive disease or fixed-rate rhythms, heart rate may not be a reliable indicator of volume status. Signs of volume depletion and impending shock include dry mucosa, poor skin turgor, decreased urine output, and mental status changes. Children will present with sunken eyes, depression of the fontanel, decrease in urine output (number of wet diapers), and decrease in alertness and activity.

Particular attention should be given to the abdominal examination. Focal abdominal pain with peritoneal findings may be due to an acute surgical abdomen with symptoms mimicking those of severe gastroenteritis. A rectal examination should be performed to detect fecal impaction, melena, or hematochezia.

*Associated with fever, abdominal pain, and fecal red blood cells or white blood cells. % indicates the estimated contribution to total cases.*

---

**CLINICAL APPROACH**

**Emergency Assessment and Stabilization**

An immediate assessment should be made of the patient’s stability, including maintenance of the airway, adequacy of oxygenation and ventilation, and circulation, with particular attention to volume status. Tachycardia, orthostatic hypotension, poor skin turgor and color, diaphoresis, and mental status changes all are characteristic of hypovolemia and hypoperfusion. Associated septic shock may contribute to the hypotension and general organ hypoperfusion, and diarrhea may be a manifestation of toxic shock syndrome. A diarrhea-associated acid-base disorder should be suspected in patients with Kussmaul respirations, a significant anion gap on basic metabolic panel reflecting a lactic acidosis from significant volume loss, or a non–anion gap metabolic acidosis associated with massive bicarbonate loss. After stabilization, a secondary survey may elucidate the potential cause of the diarrhea and direct further evaluation and treatment.
Gross blood may be consistent with invasive, infectious diarrhea but may be the harbinger of many other pathologic states that manifest with gastrointestinal bleeding. Histamine-induced skin changes may be indicative of an intestinal parasitic infection. The patient should be assessed for specific toxidromes, such as cholinergic or sympathomimetic states that may be clues to a noninfectious cause.

**Characterization of the Diarrheal Syndrome**

**Acute Infectious Diarrhea** Most viral and many bacterial agents cause a self-limited, secretory diarrhea that lasts less than 14 days and causes only mild dehydration and minimal systemic symptoms. These infections do not require extensive testing and are treated symptomatically. In the United States, monitoring of pathogens causing this type of acute gastroenteritis demonstrates that 90% of the infections are caused by norovirus species. All other potential causes of diarrhea are highly improbable unless certain historical and clinical findings are present. Bacterial and protozoan agents less commonly cause diarrhea syndromes indistinguishable from norovirus infection with a nontoxic, self-limited course. A Bayesian approach to diagnosing and treating acute diarrhea has been proposed. The clinical evaluation should screen for all factors (Table 23-1) that may change the probability of “not norovirus” from 10% to 50% or greater. With one or more of these findings

**CAUSES OF NONINFECTIONAL DIARRHEA**

**Toxins**

**Drugs**

- ACE inhibitors
- Alprazolam (Xanax)
- Antacids (Mg)
- Antibiotics
- Antidepressants
- Antiepileptic drugs
- Antihypertensives
- Antiparkinson drugs
- Beta-blockers
- Caffeine
- Cardiac antiarrhythmics
- Chemotherapy agents
- Cholesterol-lowering drugs
- Cholinergic agents
- Cholinesterase inhibitors
- Colchicine
- Digitalis
- Diuretics
- Fluorouracil
- Fluoxetine (Prozac)
- Histamine H2-receptor antagonists
- Hydralazine
- Lactulose
- Laxatives/cathartics
- Levodopa
- Lithium
- NSAIDs
- Neomycin
- Podophyllin
- Procainamide
- Prostaglandins
- Quinidine
- Ricinoleic acid
- Theophylline
- Thyroid hormone
- Valproic acid

**Dietetic Foods**

- Mannitol
- Sorbitol
- Xylitol

**Fish-Associated Toxins**

- Amnestic shellfish poisoning
- Ciguatera
- Echinodermers

**Plant-Associated Toxins**

- Herbal preparations
- Horse chestnut
- Mushrooms—*Amanita* spp.
- Nicotine
- Other plant toxins
- Pesticides—organophosphates
- Pokeweed
- Rhus barb
- Miscellaneous
  - Allergic reactions
  - Carbon monoxide poisoning
  - Ethanol
  - Heavy metals
  - Monosodium glutamate (MSG)
  - Opiate withdrawal

**Gastrointestinal Pathology**

- Appendicitis
- Autonomic dysfunction
- Bile acid malabsorption
- Blind loop
- Bowel obstruction
- Celiac disease
- Cirrhosis
- Defects in amino acid transport
- Diverticular disease
- Familial dysautonomia
- Fecal impaction
- Fecal incontinence
- GI bleed
- GI cancer
- Hirschsprung’s disease
- Inflammatory bowel disease (ulcerative colitis, Crohn’s disease)
- Intussusception
- Irritable bowel syndrome
- Ischemic bowel
- Lactose/fructose intolerance
- Malabsorption syndromes
- Malrotation
- Postsurgical
- Postvagotomy

**Endocrine-Related**

- Carcinoid syndrome (serotonin)
- Hormonal hypersecretion
- Hyperthyroidism (thyroid hormone)
- Medullary carcinoma of the thyroid (calcitonin)
- Pancreatic cholera (VIP)
- Somatostatinoma (somatostatin)
- Systemic mastocytosis (histamine)
- Zollinger-Ellison syndrome (gastrin)

**Endocrine Pathology**

- Adrenal insufficiency
- Diabetes enteropathy
- Hypoparathyroidism
- Pancreatic insufficiency

**Systemic Illness/Other**

- Alcoholism
- Amyloidosis
- Connective tissue disease
- Cystic fibrosis
- Ectopic pregnancy
- Hemolytic-uremic syndrome
- Henoch-Schönlein purpura
- Lymphoma
- Otitis media—infants
- Pelvic inflammatory disease
- Pneumonia/sepsis
- Pyelonephritis
- Scleroderma/SLE
- Stevens-Johnson syndrome
- Wilson’s disease
- Miscellaneous
  - Factitious diarrhea
  - Runner’s diarrhea

ACE, angiotensin-converting enzyme; GI, gastrointestinal; NSAIDs, nonsteroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus; VIP, vasoactive intestinal polypeptide.

DM, diabetes mellitus; EPEC, enteropathogenic E. coli; WBC, white blood cell.

Present, empirical antibiotic or other specific therapy may be indicated, as well as clinical testing to determine the exact etiologic disorder.

**Chronic Infectious Diarrhea** Persistent diarrhea is defined as that lasting for more than 14 days, and chronic diarrhea, more than 30 days. Infectious agents of persistent and chronic diarrhea include bacteria, parasites, and rarely viruses. Common bacterial pathogens include *Aeromonas*, *Plesiomonas*, *Campylobacter*, *Clostridium difficile*, *Salmonella*, and *Mycobacterium tuberculosis*. Parasites causing chronic diarrhea are colonic forms such as *Amoeba*, *Trichuris*, *Yersinia*, and *Schistosoma* species or small intestinal pathogens such as *Giardia*, *Cryptosporidium*, *Cyclospora*, *Isospora*, and *Strongyloides*. In developing countries, chronic diarrhea is more likely to have a bacterial cause. In developed countries, chronic diarrhea is caused by noninfectious disorders such as irritable bowel syndrome, malabsorption syndromes, laxative abuse, and inflammatory bowel disease. Categorization of the stool type as watery, inflammatory, or fatty may assist in proper classification of the chronic diarrhea syndrome as infectious and noninfectious. Testing for HIV or immune deficiency is important because these patients commonly present with chronic diarrhea. Evaluation should include testing for cryptosporidiosis, microsporidiosis, mycobacteria (i.e., *Mycobacterium avium* complex), herpes simplex virus (HSV), *Isospora*, *Cyclospora*, and cytomegalovirus. In addition, parasitic and helminthic infections should be ruled out.

**Noninfectious Diarrhea** Noninfectious causes of diarrhea (see Box 23-2) are responsible for approximately 15% of all cases of diarrheal illness. The distinction between infectious and noninfectious causes may not be clinically apparent. A complete evaluation should consider possible surgical pathology of the abdomen, including gastrointestinal bleeding, ischemic bowel, acute appendicitis, intussusception, ectopic pregnancy, and partial bowel obstruction. The differential diagnosis also includes possible toxic exposures or ingestions, such as heavy metal poisoning, or ingestion of plant-borne or fish-borne toxins. Endocrine pathology, such as adrenal insufficiency, hyperthyroidism, diabetic enteropathy, and
hormone-secreting tumors, and other systemic illnesses should be considered, and special attention should be directed at underlying medical conditions, medication use, and past surgical history.

Ancillary Testing

Most cases of acute diarrhea are self-limited, and laboratory and diagnostic tests should be kept to a minimum unless required for epidemiologic studies. Testing is indicated in patients who have a high probability of a “non-norovirus” clinical picture and have worrisome historical data, signs, and symptoms associated with an increased probability of those causes. Ancillary testing should never compromise empirical treatment when indicated (as discussed later on). Fever with a toxic appearance and volume depletion, blood- or mucus-containing stools, frequent voluminous stools, and other risk factors (Table 23-1) should prompt a diligent search for a specific causative disorder in order to guide appropriate therapy.8,10 A white blood cell count is rarely helpful and not sensitive or specific enough to aid in diagnostic decision-making, although hemoglobin determination is useful to screen for anemia from blood loss, and abnormalities in platelet and coagulation parameters may contribute to identification of a cause for gastrointestinal bleeding. A comprehensive chemistry panel including renal function tests can be important when significant volume loss is suspected, or when significant diarrhea has been present for 48 to 72 hours. Liver function studies, thyroid tests, serum lipase assay, and a pregnancy test may be helpful in selected cases.

Hemoccult and fecal cell count: The presence of fecal leukocytes is not specific or sensitive enough to use as the sole criterion to decide which patients with presumed bacterial gastroenteritis should be treated empirically with antibiotics. With inflammatory diarrhea of various causes, red and white blood cells are seen on stool examination. Included are bacterial, parasitic, and noninfectious causes, such as chemotherapy, radiation therapy, hypersensitivity reactions, autoimmune disorders, and inflammatory bowel disease. The presence of fecal leukocytes does not delineate which patients would benefit from empirical antimicrobial therapy. The presence of blood does not always correlate with the presence of fecal leukocytes, so reliance on positive stool guaiac test result alone as a rationale for antibiotic therapy is not recommended. The presence of blood without fecal leukocytes may indicate amebiasis, malignancies, heavy metal poisoning, fissures, hemorrhoids, bowel ischemia, or primary gastrointestinal bleeding.

Assays for calprotectin and lactoferrin, produced by leukocytes, are sensitive and specific and may be more useful than microscopic examination of the stool, but these tests are rarely, if ever, of use in the ED.9

Clostridium difficile toxin assay: This test is indicated if the patient reports recent antibiotic use. C. difficile–associated diarrhea most commonly occurs during or shortly after the antibiotic course. In 25% to 40% of cases, however, onset of the diarrhea may be delayed as long as 12 weeks after antibiotic therapy. The most commonly implicated antibiotics are cephalosporins, penicillins, and clindamycin. Although C. difficile accounts for only 10% to 20% of antibiotic-associated diarrhea, an assay for C. difficile toxin gives a positive result in nearly all cases of antibiotic-associated pseudomembranous colitis.11 Approximately 3% of adult patients and 65% of newborns may be colonized with C. difficile.

E. coli O157:H7 toxin assay: This test is considered in endemic areas and in patients with suspected hemorrhagic syndrome.12

Stool culture for bacteria: Stool cultures may be warranted in patients who are febrile, toxic-appearing, immunocompromised, at the extremes of age, experiencing a prolonged course, or not responding to conventional treatment. Studies have shown a 2% positive rate, thus proving that routine cultures are of limited value.12

Stool examination for ova and parasites: The assessment of stool for ova and parasites is not routinely recommended. This study is used in patients with chronic diarrhea (E. histolytica, Cryptosporidium); patients with a history of travel to developing countries, particularly to Nepal or areas of Russia (Cryptosporidium, Giardia, Cyclospora);12 patients with exposure to infants in day care centers (Cryptosporidium, Giardia); and patients with HIV infection (E. histolytica, Giardia).14

Giardia antigen assay and serologic testing for amebiasis may be considered in patients exposed to poor sanitation, HIV-infected patients, patients with a history of travel to developing countries, patients with a history of backpacking, and patients with day care exposures.

Urinalysis: A urinalysis and a urine pregnancy test should be obtained only when urinary tract infection is a possibility, a gastrointestinal origin for the symptoms is not clear, or pregnancy is suspected.

Radiographic studies: Plain radiographs and contrast computed tomography (CT) may be indicated for patients thought to have a surgical abdomen and to identify pathologic abnormalities, such as tumor, obstruction, free air, fistulas, blind loops, and those associated with Crohn’s disease.

Gastrointestinal referral: Referral may be indicated in the evaluation of chronic diarrhea and for workup beyond the scope of the ED (e.g., endoscopy, further stool studies, biopsy).

**EMPirical MANAGEMENT**

Oral rehydration is the treatment of choice for mild to moderate fluid losses (Fig. 23-1). Oral rehydration can be accomplished using sports beverages, commercial rehydration solutions, or a balanced clear liquid diet in the home (e.g.,

![Figure 23-1](https://example.com/ Figure 23-1. Approach to the patient with acute diarrhea. CT, computed tomography; US, ultrasonography.)
Ringer’s solution is the preferred treatment. Pediatric patients intravenous fluid resuscitation with normal saline or lactated should be avoided. The osmotic effect is counterproductive. Intake is encouraged, but foods high in simple sugars should contain excess sugars and insufficient sodium content, however, leading to an osmotic diarrhea. Beverages containing caffeine should be avoided because caffeine increases cyclic adenosine monophosphate levels and may cause a secretory diarrhea. Milk and other products containing lactose also should be avoided because viral and bacterial pathogens, responsible for many cases of diarrhea, may cause a transient lactase deficiency, leading to malabsorption and osmotic diarrhea. Food intake is encouraged, but foods high in simple sugars should be avoided because the osmotic effect is counterproductive. Foods with a high fat content may delay gastric emptying and should be avoided. The BRAT (bananas, rice, apples, and toast) diet has long been recommended, particularly with pediatric patients. Although no controlled studies have examined the efficacy of the BRAT diet, it remains a commonly recommended strategy. The pectin in the peel of apples is constipating (pectin, found in fruit peel, is the “pectate” in Kapectate), and bananas provide potassium. If this diet is used for extended periods, adequate provision of protein and energy needs of the patient becomes a concern.

In patients with evidence of more severe dehydration, intravenous fluid resuscitation with normal saline or lactated Ringer’s solution is the preferred treatment. Pediatric patients should receive a bolus of 20 mL/kg of normal saline, which may be repeated as indicated. Specific treatment for diarrhea should be directed toward the suspected cause. In patients with suspected surgical pathology, further diagnostic testing and surgical consultation may be required. With toxic exposures, treatment consists of early decontamination, supportive care, and, if appropriate, administration of specific antidotes. Other noninfectious causes of diarrhea are treated as indicated.

Because the specific pathogen causing infectious diarrhea is rarely identified in the ED, and the results of cultures are usually unavailable, any antimicrobial treatment must be empirical and guided by knowledge of the common causes of infectious diarrhea (see Table 23-1). Viral and noninvasive bacterial gastroenteritis tend to be self-limiting and require only supportive therapy. Empirical antibiotic treatment is directed against invasive bacterial and parasitic organisms that cause the greatest harm. Antibiotic treatment is initiated in patients with a suspected invasive process and severe diarrhea, systemic symptoms, fever, or abdominal pain and in patients who appear toxic. The current recommendation for empirical treatment of a systemically ill-appearing adult is ciprofloxacin, 500 mg orally twice a day, or levofloxacin, 500 mg orally every 24 hours for 3 to 5 days. Fluoroquinolones are efficacious against most organisms that cause dysenteric illnesses and have been shown to be more effective than trimethoprim-sulfamethoxazole. Fluoroquinolones should not be administered to pregnant patients or children younger than 18 years of age. The antibiotic treatment of severe gastroenteritis in children has been associated with the development of hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura if the bacterial cause is enterohemorrhagic E. coli 0157:H7, although Salmonella, Shigella, and Campylobacter also have been implicated. If possible, treatment for pediatric patients should be based on culture results with supportive care initially.

If amebic dysentery is of concern in high-risk patients (see Table 23-1), treatment with metronidazole after stool analysis for ova and parasites is recommended. In patients with a history of recent antibiotic use suspected of having C. difficile colitis, a C. difficile toxin assay followed by vancomycin or metronidazole is appropriate.

The use of antimotility agents in the treatment of acute enteritis has been controversial, with the literature divided over this issue. Patients with simple, acute viral gastroenteritis benefit from antiotility agents and often obtain significant relief of symptoms, with less fluid loss and without significant complications. Loperamide is the safest and most effective medication. Relief of symptoms is achieved much more rapidly than with bismuth subsalicylate (Pepto-Bismol) in patients with inflammatory diarrhea or antibiotic-associated colitis. In pediatric age groups, the use of opioids, loperamide, or diphenoxylate with atropine rarely has been associated with the precipitation of toxic megacolon and hemolytic-uremic syndrome. Because the beneficial effects of these medications are modest, they should be avoided or used with extreme caution in these high-risk patients.

Probiotics have been used as an alternative to traditional antibiotic therapy for diarrhea. Lactobacillus and other bacteria have proved to be effective in restoring the normal gastrointestinal flora that is disrupted during diarrhea illness. This approach has been most effective with traveler’s diarrhea and nonspecific diarrhea in children.

### DISPOSITION

Most patients with uncomplicated, acute diarrhea can be discharged home after assessment and symptomatic relief. Hospitalization rarely is required for diarrhea secondary to viral and many forms of bacterial gastroenteritis, which tend to be self-limiting. Often the exact etiologic agent of diarrhea is not identified in the ED. An understanding of common causes and their treatment and recognition of patients at risk for a more severe clinical course are essential to make the appropriate disposition. In patients with severe dehydration, hemodynamic instability, or a toxic appearance and in high-risk groups, hospital admission is warranted for continuous monitoring, further treatment, and definitive management when initial evaluation and stabilization are complete.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
PERSPECTIVE

Constipation is a symptom, not a disease. Patients and doctors often define constipation differently. Patients often use the term constipation to describe a broad set of complaints including straining, hard or infrequent stools, feeling of incomplete evacuation, and abdominal discomfort. Constipation may be acute (new for the patient) or chronic. Chronic constipation is defined as the presence of symptoms for at least 3 months. The Rome III criteria constitute a consensus definition of functional chronic constipation often used in research (Table 24-1). Attempting to identify the cause of this symptom will often result in the best chance of effective treatment and will help determine disposition. A definitive diagnosis often is not possible in the emergency department, and appropriate follow-up evaluation should be arranged in those cases. When constipation becomes severe with constant pain, some clinicians use the term obstipation. Obstipation represents the progression of the symptom of constipation toward bowel obstruction.

In the emergency department (ED), the complaint of constipation should be of concern when it represents a significant change from a patient’s own normal pattern that is creating discomfort for the patient. This change may manifest as a decrease in frequency of defecation, sudden and persistent change in the character or amount of stools (especially decrease in stool caliber), blood in the stool, or problems expelling the stool.

DIAGNOSTIC APPROACH

Differential Considerations

The causes of constipation are numerous. Causes of constipation can be divided into primary (no apparent external cause) and secondary causes (summarized in Table 24-2). These two groupings have some overlap. In the ED, patients commonly present with acute constipation due to side effects of medications or avoidance of defecation secondary to presence of painful perianal lesions such as fissures, hemorrhoids, or perirectal abscesses.

Pivotal Findings

History

A thorough, detailed history usually identifies the most likely cause of the patient’s constipation. Defining what the patient means by “constipation” is a good starting point. Essential information includes the presence or absence of alarming signs or symptoms. These include fevers, anorexia, nausea, vomiting, new onset or worsening of constipation, blood in the stool, weight loss, and a family history of inflammatory bowel disease or colon cancer.

Additional elements of the history are directed toward elucidating a possible cause. Questions about the character of the stools may reveal a decrease in caliber of the stool, suggesting possible mass lesion, or diarrhea alternating with constipation, which may indicate irritable bowel syndrome. Frequency of stools and what the patient considers “normal” should be assessed.

The review of systems may need to include questions regarding associated symptoms if no obvious cause is elicited in the cursory history. Questions directed at associated neuro-
### Table 24-1: Rome III Criteria for Functional Constipation

1. At least 2 of the following for a minimum of 3 months, with symptom onset at least 6 months before diagnosis:
   - Straining during ≥25% of bowel movements
   - Lumpy or hard stools for ≥25% of bowel movements
   - Sensation of incomplete evacuation for ≥25% of bowel movements
   - Manual maneuvers to facilitate ≥25% of bowel movements (e.g., digital evacuation, support of the pelvic floor)
   - <3 bowel movements per week
2. Loose stools rarely present without use of laxatives
3. Insufficient criteria for irritable bowel syndrome

### Table 24-2: Causes of Constipation

**Primary Causes**
- Idiopathic
- Irritable bowel syndrome
- Pelvic dyssynergia (anismus)
- Slow-transit constipation

**Neuropathic**
- Congenital anal sphincter myopathy
- Hirschsprung’s disease
- Spinal cord injury

**Obstructive**
- Anal stenosis
- Crohn’s disease
- Colon cancer
- Stricture
- Rectal prolapse

**Gynecologic**
- Large rectocele
- Pelvic relaxation

**Secondary Causes**

**Lifestyle/General Condition**
- Dehydration
- Inadequate dietary fiber
- Sedentary
- Voluntary suppression of defecation

**Medications**
- Antacids
- Anticholinergics
- Anticonvulsants
- Antidepressants
- Antihistamines
- Antiparkinsonian drugs
- Antipsychotics
- Calcium channel blockers
- Calcium supplements
- Diuretics
- Iron supplements
- Laxatives (chronic abuse)
- Nonsteroidal anti-inflammatory drugs
- Opiates

**Metabolic/Endocrine**
- Diabetes mellitus
- Hypercalcemia
- Hypokalemia
- Hypothyroidism
- Hypomagnesemia
- Porphyria
- Uremia

**Myopathic**
- Scleroderma
- Amyloidosis
- Neurolologic
- Cerebrovascular accident
- Autonomic neuropathy
- Multiple sclerosis
- Paraneoplastic neuropathy
- Parkinson’s disease
- Amyotrophic lateral sclerosis

**Psychological**
- Anxiety
- Depression
- Eating disorders
- Situational stress
- Sexual abuse

---

logic symptoms, activity level, and status of comorbid diseases may provide clues to contributing factors. A medication history is essential and should include any recent changes in dosing of any prescription medications, herbal agents, and over-the-counter (OTC) medications. Many patients experience constipation as a side effect of medication. Drugs of abuse also may cause changes in bowel patterns. Opiates are the most common cause of constipation among medications and drugs of abuse.

### Physical Examination

The physical examination should initially focus on two major aspects: the abdominal and rectal portions of the physical examination. The abdominal examination usually yields normal findings but may reveal tenderness, a mass, distention, or possibly evidence of obstruction. Bowel sounds should be auscultated.

The anorectal examination and an evaluation of the stool are the most important parts of the physical assessment. Anorectal inspection may reveal fissures, skin excoriations, hemorrhoids, or rectal prolapse. The digital rectal examination should include careful palpation for masses, and the presence or absence of pain should be noted. Other possible findings include strictures, high sphincter tone, and the presence of blood. Having the patient bear down may be helpful in assessing sphincter function and may reveal milder forms of prolapse. The quantity and the characteristics of the stool should be recorded. Testing the stool for occult blood may yield additional information, although straining at stool can produce local anal lesions and bleeding. If results of occult blood testing are positive, diverticular disease, carcinoma, and simply trauma from repeated attempts at straining all are possibilities. Patients with acute constipation who present to the ED most commonly have large amounts of hard stool in the rectum. Results of rectal examination have not been shown, however, to correlate with complaints of constipation or with evidence of colonic loading on abdominal radiographs. The rectal examination alone should not be used to confirm or exclude the presence of constipation.

### Ancillary Testing

A majority of patients who present to the ED with a chief complaint of constipation do not need any testing. Plain radiographs may provide information about extent of stool retention but also may suggest emergent diagnoses such as megacolon or volvulus. Although constipation can cause cramping and abdominal pain, plain radiographs documenting an increased stool load in the constipated patient cannot be used to rule out more serious underlying etiologic disorders, especially if the

patient has a significant amount of abdominal pain or tenderness on examination.

Clinical laboratory studies are not routinely indicated in the workup for constipation. When blood is found in the stool, a hemoglobin level may reveal an accompanying anemia, which may suggest an occult carcinoma. The white blood cell count is nonspecific and not helpful.

Patients with acute constipation for which the cause is not readily apparent should receive symptomatic treatment, with referral for outpatient evaluation and reassessment as needed. The patient who presents to the ED with chronic constipation and no alarming signs or symptoms should receive empirical treatment without any ancillary testing. Outpatient tests may eventually include blood tests to investigate metabolic or endocrine causes and possibly specialized tests such as colonic transit studies, defecography, and anorectal manometry with balloon expulsion. Consensus recommendations state that the routine use of colonoscopy to exclude organic disorders in patients with chronic constipation symptoms is not indicated, although it is still recommended for colon cancer screening in all patients older than 50 years of age.9,10

### Diagnostic Algorithm

The approach to the patient with constipation starts with assessing whether or not this symptom is accompanied by the additional symptom of abdominal pain. If such pain is present, the workup should be geared toward this symptom, which may ultimately reveal the cause of the constipation. Constipation may itself cause abdominal pain; however, this should be a diagnosis of exclusion once other, more serious potential etiologic disorders are ruled out.

Figure 24-1 presents a diagnostic algorithm. If the physical examination reveals a structural or mechanical cause, such as

---

**Figure 24-1.** Algorithmic approach to the diagnosis of constipation. ALS, amyotrophic lateral sclerosis; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CRF, chronic renal failure; IBD, inflammatory bowel disease; I&D, incision and drainage; MOM, milk of magnesia.
pain from hemorrhoids, fissures, or mass lesion, the appropriate treatment or referral is indicated; the constipation will resolve once the cause is addressed. If no obvious cause is found on examination, then determination of the presence or absence of stool in the rectal vault may be helpful. History will be very helpful in differentiating between causes such as medication side effect and possible neurologic disease.

Constipation is rarely associated with morbidity or mortality. Most bad outcomes are due to missed diagnosis of bowel obstruction or perforation. These conditions are diagnosed with physical examination, plain radiographs, and computed tomography (CT) scan if needed. Surgical consultation is needed for suspected perforation and obstruction.

**EMPIRICAL MANAGEMENT**

Treatment of acute constipation is directed toward eradicating the underlying cause and providing symptom relief. Prevention of further episodes of constipation may include recommending increased fluid intake, increased dietary fiber, and, if necessary, additional sources of bulk in the form of synthetic bulk agents. These interventions will not usually help the acutely constipated patient in the short term. Laxatives often will be required\(^\text{10}\) (see Table 24-3). Specific therapy also may include actions such as withholding a causal medication, management of an anal fissure, or draining of a perirectal abscess. Stool softeners have not been shown to be any more effective than placebo at relieving acute constipation, although they may be somewhat helpful in patients with anal fissures or hemorrhoids, which can make defecation painful.\(^\text{11,12}\)

Specific agents for symptomatic treatment of constipation are listed in Table 24-4. Most of these agents are designated category B or C as determined by the U.S. Food and Drug Administration (FDA). A consensus panel recently concluded that polyethylene glycol (category C) was the optimal laxative for pregnant women because it is effective and minimally absorbed, has few side effects, and is low risk.\(^\text{13}\) Patients who are on chronic, medically necessary medications that cause constipation (e.g., opioids in patients with chronic pain or cancer) should be on so-called bowel regimens. These regimens usually include preventive measures such as high levels of dietary fiber (e.g., in prunes or figs) as well as stimulant laxatives. Patients on chronic opioids with acute constipation may also respond to naloxone although precipitating withdrawal symptoms are possible.\(^\text{14}\) The new specific peripheral opioid receptor agents on the horizon may prove to be very useful in treating the constipation associated with chronic opioid use without reversing central actions.\(^\text{15}\) Elderly patients who are prescribed opiates from the ED for home use should be warned about constipation and given instructions to prevent and treat it.

Enemas are sometimes necessary if laxatives have failed to provide relief or if the patient has a large volume of stool in the lower colon or rectum that cannot be expelled. Warm tap-water enemas probably are the safest. For immediate relief, manual disimpaction may be necessary in some patients, especially in elderly persons with large amounts of stool present in the rectal vault. In the rare case, disimpaction may need to be performed with procedural sedation.

There are alternatives to the traditional laxatives and enemas for patients who suffer from chronic constipation. Patients with recalcitrant constipation may benefit from interventions such as acupuncture, biofeedback, and bowel training.\(^\text{16,17}\)

### Table 24-3 General Approach to Treatment of Constipation

For specific agents, dosages, and precautions, see Table 24-4.

**I. Core program for all patients**

A. Adequate intake of fluid and fiber is one key to preventing constipation. Fiber is available primarily from grains and bran cereals. Flatulence, bloating, and cramps are common side effects encountered when bran fiber is introduced.

B. Another source of bulk is from synthetic bulk agents (e.g., psyllium). Bulk agents require an adequate amount of fluid intake; otherwise, they may worsen constipation.

C. Avoid irritant laxatives as part of a core program because long-term use may decrease bowel motility. Encourage the patient to exercise and respond promptly to the urge to defecate.

**II. Individualized program—specific indications and general comments**

A. **Stimulant laxatives**: Many believe that long-term use of these agents leads to dependency and habituation, but this is not substantiated. When used appropriately, these medications are not harmful and are very effective. Senna is probably the first-line choice among this class of laxatives.

B. **Osmotic laxatives**: These agents are most commonly used for colonic preparation before bowel procedures. This class of drugs includes magnesium-containing laxatives, polyethylene glycol (PEG), and nonabsorbable sugars such as lactulose and sorbitol. These agents are safe and well tolerated. PEG has been shown to be slightly more effective than lactulose and causes less bloating and flatulence.

C. **Lubricants**: Oral mineral oil lubricants are particularly helpful in patients who have acute painful perianal lesions. The softening and coating of the stool can make passage much easier and less painful, preventing constipation. It is also helpful in elderly patients who have chronically hard stools and usually is well tolerated. Mineral oil is contraindicated in patients with swallowing problems or in those who are particularly debilitated, to prevent aspiration leading to lipid pneumonia.

D. **Stool softeners**: Stool softeners are wetting agents believed to enhance the moisture content of fecal material. Evidence exists that stool softeners are no more effective than placebo and certainly not any better than other agents available.

E. **Suppositories and enemas**: These agents are especially useful in patients who tend to have trouble expelling soft stool from the rectum. Glycerin suppositories may have a soothing effect and be helpful in patients with constipation caused by local, painful perianal lesions. Tap-water enemas or soapsuds enemas are helpful when disimpaction is necessary.

**DISPOSITION**

Constipation is appropriately treated at home, and only the most severe cases require disimpaction or enema treatment in the ED. With complications or presence of a serious disorder as a cause for the constipation, such as fecal impaction beyond that able to be resolved by digital disimpaction, megacolon, volvulus, or bowel obstruction, the patient should be admitted to the hospital for further evaluation and treatment.

</table>
Jaundice affects patients of all ages, from neonates to the elderly. It is not a common chief complaint; however, the jaundiced patient may present with a related symptom such as abdominal pain, pruritus, or substance ingestion. Jaundice is the manifestation of elevated serum bilirubin, so an understanding of the metabolism of bilirubin is crucial for the emergency evaluation and management of jaundice.

### Bilirubin Metabolism

Bilirubin is generated from heme products, primarily senescent red blood cells. A small portion is derived from myoglobin and maturing erythroid cells. Within the reticuloendothelial system, heme is oxidized to biliverdin, which is then converted to bilirubin. Bilirubin forms a tight but reversible bond with albumin in circulation. It is passively taken into the hepatocytes, where it undergoes glucuronidation. This conjugated fraction is secreted into the biliary system and emptied into the gut. Colonic bacteria metabolize the major portion of the bilirubin to urobilinogen and stercobilin. Stercobilin is excreted in the stool and urobilinogen is reabsorbed and excreted in the urine. The remaining conjugated bilirubin is deconjugated and reenters the portal circulation to be taken up again by the liver (enterohepatic circulation).

In the laboratory, conjugated bilirubin is the fraction that reacts directly with reagents whereas unconjugated bilirubin requires the addition of an accelerator compound. They are reported as direct and indirect fractions, respectively.

### Pathophysiology

Clinical jaundice usually is not evident until the serum bilirubin concentration rises above 2.5 mg/dL. It is observed in tissues with high albumin concentrations, for example, the skin and eyes. It is absent in albumin-poor fluids, such as tears or saliva. The physiology of bile metabolism may be altered on four principal levels: overproduction of heme products, failure of the hepatocyte to take up the bilirubin for processing, failure of the hepatocyte to conjugate or excrete bilirubin, or an obstruction of biliary excretion into the intestine. Unconjugated bilirubin that is not bound to albumin can cross the blood-brain barrier, causing adverse neurologic effects ranging from subtle developmental abnormalities to encephalopathy and death. The risk of neurotoxicity is increased by conditions that favor the unbound fraction of unconjugated bilirubin, including hemolysis, hypoalbuminemia, acidemia, and drugs that bind competitively to albumin. Conjugated bilirubins are not neurotoxic, although they may indicate serious disease.

### Diagnostic Approach

#### Differential Considerations

The three major diagnostic categories to consider as causes of jaundice are biliary obstructive disorders, liver injury or dysfunction, and hematologic disorders. Figure 25-1 outlines a laboratory-based approach to differentiating among these three categories.

#### Pivotal Findings

The pivotal findings related to history, physical examination, and ancillary testing are listed in Figure 25-2.

### History

Patients may be asymptomatic at presentation or have nonspecific symptoms, such as pruritus, malaise, or nausea. There are a few symptom complexes that, if present, can help narrow the differential diagnosis. Jaundice with abdominal pain suggests significant hepatic inflammation. New-onset painless jaundice is the classic presentation for a neoplasm involving the head of the pancreas. Patients may complain of ill-fitting clothing because of weight loss or increasing abdominal girth related to ascites. The patient or caregiver may note personality changes or confusion, suggestive of hepatic encephalopathy. Unexplained liver failure and jaundice may be the downstream sequelae of an intentional overdose of acetaminophen taken 48 to 72 hours (or more) earlier.

### Physical Examination

A thorough examination should be performed in patients presenting with jaundice, because the physical findings can help narrow the differential diagnosis. Pertinent examination findings are summarized in Figure 25-2. Jaundice is first apparent sublingually, on the hard palate, and in the conjunctiva. From there, it spreads caudally. Studies in both adults and neonates suggest that the “level” of cephalocaudal progression of jaundice cannot accurately estimate the serum bilirubin concentration.\(^1\)\(^2\)
Fever with right upper quadrant tenderness suggests cholangitis. In this clinical scenario, the liver should not be engorged. A large tender liver may represent an exacerbation of acute or chronic hepatitis or malignant infiltration. A palpable gallbladder, a rare finding, suggests chronic cholestasis or malignancy. The presence of splenomegaly suggests hemolysis, malignancy, or portal hypertension. Ascites may be associated with acute or chronic liver disease. Ascites associated with abdominal tenderness raises suspicion for spontaneous bacterial peritonitis. Rapid onset of hepatomegaly and ascites may indicate portal vein thrombosis (Budd-Chiari syndrome). Jaundice associated with a large pulsatile abdominal mass may indicate a rapidly enlarging or ruptured abdominal aortic aneurysm. The patient’s mental status should be assessed for evidence of hepatic encephalopathy.

Physical examination findings associated with chronic liver disease and cirrhosis include spider angiomas, gynecomastia, testicular atrophy, and caput medusae. Excoriations from scratching in attempts to relieve pruritus suggest chronic liver disease. Asterixis, a sign of hepatic encephalopathy, usually is found only in patients with chronic liver disease. Table 25-1 summarizes the clinical stages of hepatic encephalopathy.

**Ancillary Testing**

Figure 25-1 lists the laboratory tests that should be considered in the evaluation of the patient with jaundice. Alkaline phosphatase (AP) also can be elevated in diseases affecting bone or the placenta in the first trimester. In the setting of isolated elevated AP, increased serum gamma-glutamyl transpeptidase (GGT) or 5′-nucleotidase points to a hepatic source. A reticulocyte count and evaluation of the peripheral blood smear may identify hemolysis. In the setting of toxic ingestion or unexplained hepatocellular injury, serum acetaminophen concentration level is indicated. Rapid stool guaiac testing should be performed to assess for the presence of gastrointestinal bleeding. Patients with altered mental status should have a rapid bedside glucose assessment in addition to determination of

---

A benign hereditary condition characterized by hyperbilirubinemia and jaundice due to inadequate hepatic conjugation of bilirubin.
serum ammonia concentration. Although elevated serum ammonia may aid in diagnosis, the degree of hyperammonemia has not been shown to correlate with the degree of encephalopathy. In the presence of abdominal tenderness and ascites, ascitic fluid should be tested for cell count, Gram staining, culture, and protein. Two sets of blood cultures should be obtained in patients with fever and jaundice. If the patient appears ill or there is evidence of gastrointestinal bleeding, type and screen or type and crossmatch studies should be performed.

Imaging

The best radiologic study for the emergent evaluation of obstructive biliary disease remains somewhat controversial. Both ultrasonography (US) and computed tomography (CT) are available in the emergency department (ED), and each has its advantages. The choice of imaging procedure depends on the pretest probability of biliary obstruction and on the index of suspicion of malignancy. In cases in which the probability of malignant obstruction is high, CT is the preferred imaging methodology. It is more sensitive than US in locating the site of the obstruction. Additionally, it is 70% accurate in staging disease and determining resectable versus unresectable disease. Patients with a high likelihood of benign obstruction are best screened with US. It is safe, rapid, and less expensive and less invasive than CT. Some common duct stones may be missed with US, but it is as sensitive as CT in determining the presence of obstruction. US with Doppler flow can detect obstruction of the hepatic, portal, and splenic veins. Sonographic features that suggest acute cholecystitis include presence of pericholecystic fluid and gallbladder wall thickening. If gallstones are present on ultrasound images, a sonographic Murphy sign has a positive predictive value of 90% for acute cholecystitis. In patients with low or intermediate clinical likelihood of mechanical obstruction, US is the preferred modality to evaluate whether or not biliary obstruction is present. CT is preferred if the entire abdomen needs to be evaluated.

### Differential Diagnosis

Using a systems approach, jaundice can be classified into critical, emergent, and nonemergent categories (Table 25-2). Patients are considered to be critically ill if they present with jaundice and any of the following: altered level of consciousness, hypotension, fever with abdominal pain, or active bleeding. Any patient with a new triad of jaundice, encephalopathy, and coagulopathy is considered to have fulminant hepatic failure. In general, these patients have no previous history of liver disease and experience sudden onset of illness or toxic exposure that leads to hepatic necrosis. The time course from insult to fulminant hepatic failure ranges from 1 to 8 weeks. Patients with fulminant hepatic failure require aggressive stabilization, consideration for toxic exposures, and admission to an intensive care unit or possible transfer to a center with liver transplantation capabilities.

*In Wilson’s disease, hereditary deficiency of ceruloplasmin causes copper to accumulate in the liver, leading to fulminant hepatic failure. AAA, abdominal aortic aneurysm; HELLP, hemolysis, elevated liver enzymes, low platelets.

**EMPIRICAL MANAGEMENT AND DISPOSITION**

Specific therapies depend on the likely clinical entity causing the jaundice (Fig. 25-3). The patient with depressed mental status should have bedside glucose testing. If mental status remains significantly depressed, endotracheal intubation for maintaining airway patency or protection may be required.

Intravenous access should be obtained immediately, and crystalloid infusion may be indicated in the hypotensive patient. A quick assessment of volume status is required because hepatic congestion with jaundice can occur in the setting of congestive heart failure. Owing to the risk of coagulopathy, compressible sites should be used for central venous access. Significant bleeding from any source requires aggressive management. Crystalloid infusion is initiated and continued until blood products become available. Coagulopathy should be corrected with fresh frozen plasma and blood volume repleted with packed red blood cells.

If ascites is present, diagnostic paracentesis should be considered to rule out spontaneous bacterial peritonitis (SBP). This disease can have a subtle presentation and may be missed without a diagnostic paracentesis. The presence of more than 250 polymorphonuclear cells per cm³ of ascitic fluid is diagnostic for SBP. The empiric antibiotic of choice is a third-generation cephalosporin.⁴

Patients with jaundice and elevated transaminase levels out of proportion to the elevation of alkaline phosphatase have a hepatocellular injury pattern. Liver failure with hepatic encephalopathy, if present, can be treated with lactulose, either 60 mg orally or 300 mg by retention enema. Patients with fulminant hepatic failure should be admitted to the intensive care unit or possibly transferred to a liver transplantation center.

Even in the absence of acute liver failure, patients with encephalopathy or unstable vital signs should be hospitalized. On the basis of laboratory data alone, patients with new-onset jaundice should be hospitalized if transaminases are greater than 1000 IU/L, the bilirubin exceeds 10 mg/dL, or there is evidence of coagulopathy. Any of these laboratory abnormalities suggests significant hepatic dysfunction. Patients with hepatitis or cholestatic jaundice may be managed as outpatients if they have a normal mental status and stable vital signs, are able to tolerate oral fluids, have no evidence of acute bleeding, and have no complicating infectious process. Intravenous fluids and antiemetics may be required in the ED. Medications with potential hepatotoxicity, particularly acetaminophen, should be avoided.

If the laboratory evaluation and diagnostic imaging point to an obstructive picture, ascending cholangitis must be ruled out. If it is suspected, blood cultures should be obtained, followed by prompt administration of broad-spectrum antibiotics with coverage for gram-negative aerobes and anaerobes. Patients with this disorder usually require emergent decompression by means of endoscopic retrograde choangiopancreatography (ERCP) or cholecystostomy, which dramatically improves survival.⁵ Some stable patients can undergo a trial of antibiotics and have drainage performed subacutely.⁶ However, conservative treatment is more likely to fail in patients older than 75 years or chronic smokers.⁷ Patients with extrahepatic obstructive jaundice without cholangitis should be admitted for drainage. ERCP is therapeutic for benign obstructions such as gallstones or strictures. Patients with obstructive jaundice due to malignancy also benefit from biliary decompression, whether operative, endoscopic, or palliative. Once jaundice develops, malignancy is associated with more advanced disease and increased morbidity.
Biliary drainage has been correlated with improvements in cardiac function and, not insignificantly, food intake. In patients with obstructive jaundice secondary to malignancy, preoperative drainage is not beneficial in those undergoing surgery. Palliative biliary drainage is recommended for patients who are not surgical candidates.

Endoscopic drainage with biliary stenting has been found to result in fewer complications, although the rate of recurrent obstruction is higher than with percutaneous drainage.

In general, patients with uncomplicated cholecystitis should receive intravenous fluids in the ED, parenteral analgesics, and antiemetics as needed and should be hospitalized. For uncomplicated cholecystitis, antibiotic therapy usually is not indicated. Patients with temperature greater than 38.8°C (102°F), a toxic appearance, or frank sepsis should receive broad-spectrum antibiotic therapy with coverage for enteric pathogens, streptococcal species, and anaerobes. These patients should undergo emergent imaging and consultation with a surgeon or gastroenterologist.

Choledocholithiasis, presence of a stone in the common bile duct, may not be as easily visualized by sonography but is suggested by significant obstructive signs and symptoms and dilation of the common bile duct beyond 6 mm. Affected patients require hospitalization for possible ERCP and cholecystectomy.

In immune-mediated hemolytic anemia, appropriate cross-matching may be difficult and fatal if not done properly. The decision to transfuse should be based on the achievable level...
of oxygenation and the feasibility of instituting alternative treatments. An urgent hematology consultation is recommended. In the case of drug-induced hemolytic anemia, the mainstay of treatment is removal of the offending agent. For patients with glucose-6-phosphate deficiency, blood transfusions are rarely indicated, and the focus of management should be on maintaining urine output to prevent renal failure. Patients with hemoglobinopathies rarely require transfusion therapy unless they present with severe anemia without evidence of reticulocytosis. Fluids, oxygen, and analgesics can be given for an acute crisis.

SPECIAL POPULATIONS

One specific presentation that warrants discussion is the pregnant patient who presents with jaundice. Normal physiologic changes in pregnancy have little effect on the liver, so jaundice always indicates serious pathology. Jaundice can occur in pregnancy as a result of any of the conditions discussed earlier, as well as conditions specific to pregnancy, such as hyperemesis gravidarum, acute fatty liver of pregnancy, and intrahepatic cholestasis of pregnancy.

Hyperemesis gravidarum usually manifests in the first trimester and, in severe cases, can be associated with elevated serum bilirubin. The exact mechanism for jaundice is unknown but is likely to be related to malnutrition and impaired excretion of bilirubin. ED treatment is unchanged in these cases: hydration and antiemetics. Patients with hyperemesis and jaundice should be admitted for intravenous hydration.

Intrahepatic cholestasis of pregnancy is an idiopathic cause of jaundice that occurs early in the third trimester. It manifests with pruritus mainly on the trunk, extremities, palms, and soles, followed by jaundice after 1 to 4 weeks. Other features of obstructive jaundice such as acholic stools and dark urine may be present. Laboratory analysis reveals a cholestatic picture. Affected patients are at increased risk for preterm delivery and intrauterine fetal demise and should therefore be managed in conjunction with the obstetric team or transferred to a center capable of caring for premature neonates. Specific treatments include cholestyramine for pruritus and vitamin K.

Acute fatty liver of pregnancy (AFLP) occurs in the third trimester and is characterized by accumulation of microvesicular fat within hepatocytes. It is rare, occurring in 1 in 13,000 deliveries. There is a slight predilection toward primiparous and multiple gestation pregnancies. Clinical manifestations include nausea, vomiting, right upper quadrant or epigastric pain, malaise, anorexia, and jaundice progressing to fulminant hepatic failure and encephalopathy. Treatment consists of prompt delivery. Jaundice and liver dysfunction may progress after delivery but generally resolve. AFLP generally does not recur in subsequent pregnancies. Liver transplantation has been successful for this condition.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Women of childbearing age who present with low abdominal pain often have pathologic conditions related to the female reproductive system or bladder, although additional causes must also be considered. Potential etiologic disorders range from the very benign to the immediately life-threatening. Pregnancy presents its series of considerations, and pregnancy status should be determined in all patients.

Epidemiology

Acute pain due to pelvic pathology is common, although the presenting complaint is often abdominal pain or lower abdominal pain; a complaint of low back pain may also signal pelvic pathology. A flare of chronic pelvic pain may manifest as an acute process.

In a survey of reproductive-age adult women, 39% reported that they experience nonmenstrual pelvic pain at least sometimes.1 Among women who present to an emergency department (ED) and receive a gynecologic diagnosis, 24% of those diagnoses are for pelvic inflammatory disease (PID), 23% for lower genital tract infections (e.g., cervicitis, candidiasis, Bartholin’s abscess), 12% for menstrual disorders, 12% for noninflammatory ovarian and tubal pathology (including cysts and torsion), and 4.3% for ectopic pregnancy.2 In the general population, annually 5.8 of every 1000 women present to an ED and receive a diagnosis of PID, and 1.1 of every 1000 women are diagnosed with an ectopic pregnancy.2 Younger patients and those with multiple sexual partners are more likely to have PID, and a previous episode increases the likelihood of a subsequent episode.3 The risk of ectopic pregnancy is higher in women who have had PID, pelvic surgery, or an intrauterine device. Heterotopic pregnancy is of special concern in women undergoing fertility treatment.4 Common nongynecologic diseases, such as appendicitis, diverticulitis, urinary tract infection, and urolithiasis, remain important considerations in the woman with acute pelvic pain. Box 26-1 lists conditions accounting for pelvic pain in most women.5,6

Some causes of pelvic pain may lead to serious sequela. PID carries the short-term risk of tubo-ovarian abscess, and the long-term risks of impaired fertility, chronic pelvic pain, and increased predisposition to ectopic pregnancy.3 Rupture of an ectopic pregnancy or a hemorrhagic ovarian cyst may be acutely life-threatening. Unrecognized abuse may have serious or lethal consequences as well.

Pathophysiology

The female pelvis contains the vagina, uterus, fallopian tubes and ovaries, ureters and urinary bladder, and sigmoid colon and rectum, as well as components of the musculoskeletal system. Although pelvic pain often originates from the reproductive organs, it may arise from any structures that lie adjacent to or course through the pelvis. Visceral pain afferents supplying the pelvic organs have common innervation with the appendix, ureters, and colon. Their significant overlap makes accurate localization difficult for both patient and clinician. Pain may be initiated by inflammation, distention, or ischemia of an organ, or by spillage of blood, pus, or other material into the pelvis. Parietal pain develops when the afferent nerves in the parietal peritoneum adjacent to an affected organ are stimulated.

Differential Considerations

The differential diagnosis of pelvic pain is broad in scope (see Box 26-1). Most causes of pelvic pain fit into three categories, however: (1) those that originate in the reproductive tract, (2) those that originate in the urinary tract, and (3) those that originate in the intestinal tract. Within the reproductive tract, a subset of causes of pelvic pain is only found in pregnancy; the pregnancy test is therefore a key branch point in the diagnostic process. Potential pregnancy-related disorders can be divided into complications of early pregnancy and complications that occur further along in pregnancy. Although the specific cause of pelvic pain is not always determined at the initial ED visit, an organized approach usually leads to the confirmation or exclusion of disorders most likely to result in significant morbidity.

Pivotal Findings

It is rare that any particular finding on history or physical examination (summarized in Table 26-1) is reliable enough to conclusively make or exclude a particular diagnosis, so ancillary testing (beyond a simple pregnancy test) is commonly required in the evaluation of patients with acute pelvic pain. The bimanual examination may at times provide important and convincing information. Unfortunately, however, findings on pelvic examination are somewhat subjective and unreliable,7,8 and the test may be more helpful to localize the process to one side or the other, or to help focus the workup of the...
Reproductive Tract
- Ovarian torsion
- Ovarian cyst

pathologic process to the reproductive organs. For instance, tenderness on examination that seems to arise from the right ovary may be appropriately used to guide the subsequent workup, perhaps ordering a pelvic ultrasound study. The lack of certainty of the findings on the bimanual examination, however, does not allow the examiner to completely exclude appendicitis, especially if the pelvic ultrasound study fails to identify a clear explanation for the pain.

A sequential approach, as outlined next, allows the clinician to progressively limit the diagnostic possibilities until a sound provisional diagnosis is reached.

Symptoms

The location of pain and the radiation pattern are often helpful in focusing the differential diagnosis toward a specific cause or group of causes. Lateral pelvic pain usually is related to a process in the tube or ovary. In right-sided pain, appendicitis is considered, and in left-sided pain (especially in patients older than 40 years of age), the differential diagnosis includes diverticulitis and colitis. Urolithiasis may also manifest as lateral pelvic pain, especially when the stone is impacted at the ureterovesical junction. Central pelvic pain usually is due to processes involving the uterus or bladder, or involving both adnexae. Pain radiating to the rectum may be secondary to pooling of fluid or blood in the cul-de-sac. Diffuse pain may occur with a bilateral process, such as PID, or with diffuse peritonitis secondary to infection or intra-abdominal hemorrhage.

Information regarding the onset and duration of pain may also be useful. Patients with uncomplicated appendicitis (without perforation or abscess) typically present within 48 hours of symptom onset. Sudden-onset pain suggests acute intrapelvic hemorrhage, cystic rupture, or ovarian torsion. Gradual-onset pain is more consistent with inflammation (such as in PID) or obstruction. Chronic or recurrent pain is consistent with endometriosis, recurrent ovarian cysts, or a persistent ovarian mass. The quality of pain may differentiate the crampy, intermittent pattern of muscular contractions along a hollow viscus (arising from, e.g., uterine, ureteral, or bowel pathology) from the steady, progressive pain associated with inflammatory or neoplastic causes, but this finding is highly variable. Pain associated with PID often manifests at the end of menses. Ovarian cyst pain may fluctuate through several menstrual cycles, finally manifesting as rupture, which often occurs in the middle of the menstrual cycle.

A complaint of fever and chills is more common with an infectious process. Nausea and vomiting occur more frequently when the process originates within the gastrointestinal tract but also may accompany ovarian torsion, ureteral colic, other causes of severe pain, and pregnancy. Dysuria and frequency occur in many local vulvar and vaginal processes, such as herpesvirus infection, candidiasis, and other types of vulvovaginitis, but urgency typically signals an irritated bladder or urethra, focusing attention on the urinary tract.

Information about the patient’s last menstrual period, pattern of menses, and sexual activity pattern is useful, although such data cannot be used to rule out pregnancy. Accordingly, a pregnancy test is always indicated except in women who have had a hysterectomy or are clearly postmenopausal. In a pregnant patient, the obstetric history may provide some helpful diagnostic clues. Recurrent spontaneous abortion or previous ectopic pregnancy increases the likelihood of these conditions, respectively. Patients who are actively undergoing infertility treatment are at increased risk for ectopic pregnancy, heterotopic pregnancy, ovarian torsion, and ovarian hyperstimulation syndrome. Round ligament pain usually is noted in the second trimester. Postpartum patients are at increased risk for endometritis.

The presence, quantity, and duration of associated vaginal bleeding should be ascertained. (See also Chapters 27 and 176.) In a nonpregnant patient, bleeding may be associated with PID, trauma, dysfunctional uterine bleeding, or cervical or uterine cancer. In a pregnant patient, bleeding may be associated with a subchorionic hemorrhage in an otherwise viable pregnancy or with an ectopic pregnancy or a nonviable intrauterine pregnancy (which may continue to cause bleeding after expulsion of the uterine contents, especially if any products of conception are retained), or later in pregnancy with placenta previa or abruption. In some cases, the amount of bleeding may be substantial enough to necessitate blood transfusion and surgical intervention.

As part of the past medical history, any recent procedures should be ascertained. All women are interviewed in private to permit disclosure of sensitive information, such as a known pregnancy or recent abortion. The onset of pelvic pain shortly after uterine instrumentation increases the possibility of uterine perforation or infection. Sexual history is important, with an emphasis on recent sexual contact and previous history of sexually transmitted diseases.

Signs

The physical examination is directed toward the abdomen and pelvis. Pelvic examination is performed in virtually all patients, including pregnant patients at less than 20 weeks of gestation.

CBC, complete blood count; CMT, cervical motion tenderness; CRP, C-reactive protein; CT, computed tomography; ED, emergency department; ESR, erythrocyte sedimentation rate; β hCG, β human chorionic gonadotropin; IUD, intrauterine device; PID, pelvic inflammatory disease; RLQ, right lower quadrant; T&C, type and crossmatch; TOA, tubo-ovarian abscess; US, ultrasonography; UTI, urinary tract infection.
Pregnant patients beyond 20 weeks of gestation with complaints of vaginal bleeding undergo transabdominal pelvic ultrasound study for placental localization before the pelvic examination (see Chapter 27). Timely obstetric consultation should be obtained for patients beyond 20 weeks of gestation.

Abnormal vaginal discharge may be seen in a variety of conditions, including vaginitis, cervicitis, endometritis, and PID more generally, as well as retained foreign body. Cervical motion tenderness most commonly indicates reproductive tract inflammation, but irritation of adjacent structures (e.g., cystitis, appendicitis) also may give rise to this finding. Although an open os is most consistent with an incomplete or inevitable abortion, it does not definitively exclude an ectopic pregnancy. A large uterus in a nonpregnant patient may indicate fibroids. Fundal tenderness often is difficult to distinguish from cystitis but could suggest endometritis or necrotic fibroids. Adnexal masses and tenderness suggest cystic disease, as well as ectopic pregnancy, tubo-ovarian abscess, and torsion, especially if these findings are unilateral.

The constellation of bilateral lower abdominal tenderness, bilateral adnexal tenderness, and cervical motion tenderness is classically associated with PID, particularly when onset of the pain occurs during or just after menstruation, although the diagnosis may (and often should) be made without the presence of all three signs.

**Laboratory Tests**

A pregnancy test is required in almost all patients. A positive test may indicate intra- or extraterine pregnancy or, rarely, molar pregnancy or cancer. Urine dipstick testing of a clean-catch specimen can be used to identify pyuria, typically seen in the setting of urinary tract infection, or hematuria, which is consistent with urolithiasis and also hemorrhagic cystitis. The absence of hematuria does not rule out a ureteral stone, although it lowers the likelihood. Urinalysis should be performed in all pregnant patients, even if their symptomatology does not include urinary tract complaints.

Patients who may be hemorraging either internally or externally should have blood drawn for a hemoglobin and hematocrit, as well as for typing and crossmatching.

Patients with a positive pregnancy test should undergo formal ultrasound assessment or bedside ED ultrasound examination to evaluate for ectopic pregnancy. Identification of an intrauterine pregnancy by ultrasound imaging excludes ectopic pregnancy with a high degree of certainty. Heterotopic pregnancy is exceedingly rare in patients who are not undergoing assisted reproduction. Conversely, a patient with a positive pregnancy test result in whom a definite intrauterine pregnancy cannot be seen is presumed to have an ectopic pregnancy until proved otherwise. Furthermore, presence of free intra-abdominal fluid on ultrasound images is consistent with hemorrhage from either an ectopic pregnancy or a ruptured ovarian cyst and must be addressed expeditiously.

**DIAGNOSTIC ALGORITHM**

The algorithm in Figure 26-1 is designed to help focus further testing and progress to a rational provisional diagnosis. It is not unusual, however, for common diseases to present in uncommon ways or for more than one disease to be present, and tests

![Figure 26-1. Diagnostic algorithm for acute pelvic pain. CT, computed tomography; FAST, focused assessment with sonography for trauma; GYN, gynecology; βhCG, β human chorionic gonadotropin; Hgb, hemoglobin; IUP, intrauterine pregnancy; IV, intravenous; OB, obstetrics; PID, pelvic inflammatory disease; US, ultrasound; UTI, urinary tract infection.
must be interpreted carefully in the context of the individual patient’s presentation. As examples, patients with a positive result on urine dipstick testing may have appendicitis, and pregnant patients may suffer from ovarian torsion. With certain diseases, such as endometriosis, definitive testing is not available in the ED, and the patient’s history may become the most important discriminator.

After an initial history and physical examination, the pregnancy test determines the subsequent priorities. If the patient is in early pregnancy, an ectopic pregnancy is the most emergent diagnosis to consider. Bedside or formal ultrasound assessment may rapidly confirm an intrauterine pregnancy, in which case a threatened abortion is most likely, although unilateral pain may prompt further evaluation for torsion. An empty uterus on ultrasound imaging (or any ultrasound study that cannot confirm a definite intrauterine pregnancy) is consistent with both an ectopic pregnancy and a spontaneous abortion; a very normal pregnancy is also possible. Later in pregnancy, formal ultrasound study often is indicated, and many women whose pregnancies are past 20 weeks’ gestation will require observation with monitoring.

Nonpregnant patients with pain that seems to be gynecologic in nature must be assessed for hemorrhage from a ruptured ovarian cyst; for ovarian torsion; and for infection, including cervicitis, endometritis, salpingitis, and tubo-ovarian abscess. Although the history and physical examination often are sufficient to diagnose infection, formal ultrasound assessment usually is required if torsion or tubo-ovarian abscess is suspected. Ultrasound findings also may support a diagnosis of PID if evidence of salpingitis is noted, or of a ruptured cyst if a characteristic ovarian appearance is combined with presence of a small amount of free fluid. Although not as reliable as CT scanning, the ultrasound study also may be used to examine the appendix.

Because in practice it is difficult to differentiate some gynecologic causes of pain from classic intra-abdominal causes (such as right ovarian pathology from appendicitis), the workup often will require an ultrasound study or a CT scan, or both. If the cause appears to be most likely gynecologic, then an ultrasound exam of both the ovary and the appendix is more reasonable, followed by a CT scan if the ultrasound findings are negative and the presentation is possibly consistent with appendicitis. Patients whose pain does not seem to be from the reproductive tract usually are found to have urinary infections or stones, abdominal sources of pain (see Chapter 21), or musculoskeletal pathology, or may be suffering from abuse or depression.

If the available data either do not make sense or conflict with the clinical gestalt, execution of the following three steps should be considered: (1) Ensure that emergent, life-threatening diagnoses have been addressed (e.g., is a reliable, negative pregnancy test recorded, so that ectopic pregnancy is ruled out?). (2) Move back up the algorithm and reassess whether the presentation may be atypical (e.g., is the examiner confident that appendicitis is not a consideration?). (3) If it seems reasonable that emergent causes are unlikely and sufficient consideration was given to less likely etiologic disorders without uncovering an apparent cause, review the possibility of depression or abuse before disposition. Follow-up planning for all patients is recommended.

EMPIRICAL MANAGEMENT

An algorithm for management of patients with acute pelvic pain is presented in Figure 26-2. Patients who are in extremis are most likely to be hemorrhaging, although on occasion their critical condition arises from septic shock. Presentations related to vaginal bleeding are discussed in Chapter 27. Ectopic pregnancy, placental abruption, and hemorrhagic ovarian cyst also may cause life-threatening hemorrhage with no or minimal vaginal bleeding. Patients with these disorders need rapid treatment with fluid and blood products and may require surgical intervention before stabilization can be achieved. A bedside ultrasound assessment by an appropriately trained operator may help the clinician reach the presumptive diagnosis expeditiously. The obstetric-gynecologic service should be consulted promptly. Septic shock may be a consequence of abdominal or pelvic processes and may require both general surgical and gynecologic consultations, as well as admission to an intensive care setting.

In both critical and noncritical patients, early administration of analgesia is advisable, both for patient comfort and to improve the yield of examinations. Intravenous opioids, such as morphine, are rapid and effective, titratable, and safe in pregnancy. Patients who do not appear ill and for whom a sound provisional diagnosis is reached may be discharged with close follow-up and appropriate precautions. However, pregnant patients who are at more than 20 weeks of gestation should be referred to the obstetrics service for observation. Abdominal trauma in pregnancy, especially in patients who present later in pregnancy, arouses additional concerns not addressed in this chapter.

The author would like to thank Robert Dart, MD, the previous author for this chapter.

Vaginal bleeding is one of the most frequent chief complaints of women presenting for emergency care. Normal vaginal bleeding occurs cyclically in women who have achieved menarche, mean age 12.5 years, until menopause, mean age 51 years, in North America. The normal cycle, defined as the first day of bleeding of one cycle to the first day of bleeding of the next cycle, lasts 28 days, plus or minus 7 days, and average volume of blood loss is 60 mL. Vaginal bleeding is defined temporally as midcycle (ovulatory), premenstrual, menstrual, and postmenstrual. Abnormal vaginal bleeding is classified on the basis of the duration, amount, and frequency of bleeding (Table 27-1). It occurs in women of all ages, and it can result from a number of causes, including anatomic abnormalities, complications of pregnancy, malignancies, infections, systemic diseases, and endocrinologic imbalances. Typically, premenarchal or postmenopausal vaginal bleeding is rarely life-threatening, but bleeding as a complication of pregnancy has a significantly increased risk of morbidity and mortality for the mother and fetus.

### Epidemiology
Approximately 5% of women aged 30 to 45 years will see a physician for vaginal bleeding. Nonpregnancy causes are classified as ovulatory, anovulatory, and nonuterine. Menorrhagia secondary to anovulation is seen in 10 to 15% of all gynecologic patients. It is common in perimenarchal and perimenopausal women, as well as in patients with endocrine disorders, polycystic ovary syndrome, exogenous hormone use, and liver or renal disease. Nonuterine bleeding must also be considered. Approximately 20% of all pregnant patients have vaginal bleeding before the 20th week of gestation; more than 50% of these women spontaneously abort. Vaginal bleeding is reported in 50 to 80% of ectopic pregnancies. Ectopic pregnancy is the most common cause of maternal death in the first trimester of pregnancy, accounting for 9% of pregnancy-related maternal deaths in the United States, and the second leading cause for maternal mortality overall, after postpartum hemorrhage. Teenagers and women of color have the highest risk of death related to ectopic pregnancy. Vaginal bleeding after the 20th week of gestation occurs in approximately 4% of pregnancies; approximately 30% of cases are due to placental abruption (abruption placentae), and 20% are due to placenta previa. Postpartum hemorrhage accounts for nearly 30% of pregnancy-related maternal deaths. The most common cause of postpartum hemorrhage in the first 24 hours is uterine atony. After 24 hours, retained products of conception are frequently the etiology.

### Pathophysiology
#### Pregnant Patients
The differential diagnosis of vaginal bleeding in early pregnancy (before the 20th week of gestation) includes ectopic pregnancy; threatened, inevitable, missed, or incomplete abortion; implantation bleeding; cervicitis; cervical conditions such as polyp or ectropion; bleeding from the urinary or gastrointestinal tract; and cervical carcinoma. Risk factors for ectopic pregnancy should increase clinical suspicion but are often absent. These include tubal abnormalities due to past infection or surgical scarring and assisted reproductive techniques. Disruption of the blood supply to the ectopic gestational sac can cause hemorrhage into the fallopian tube, or the size of the developing sac fetus can lead to rupture through the tubal wall.

Spontaneous abortion is the most common complication of pregnancy and is defined as the passing of a pregnancy prior to completion of the 20th gestational week. It implies delivery of all or any part of the products of conception, with or without a fetus weighing less than 500 g. Threatened abortion is bleeding of intrauterine origin occurring before the 20th completed week, with or without uterine contractions, without dilatation of the cervix, and without expulsion of the products of conception. Complete abortion is the expulsion of all of the products of conception before the 20th completed week of gestation, whereas incomplete abortion is the expulsion of some, but not all, of the products of conception. Inevitable abortion refers to bleeding of intrauterine origin before the 20th completed week, with dilatation of the cervix without expulsion of the products of conception. In missed abortion, the embryo or fetus dies, but the products of conception are retained in utero. In septic abortion, infection of the uterus and sometimes surrounding structures occurs.

Placental abruption can occur spontaneously or secondary to abdominal trauma with transmission of forces to the uterus. An increased incidence is seen in association with cocaine use, hypertension, preeclampsia, HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome, smoking, increased maternal age, and abnormal implantation of the placenta (e.g., placenta previa, accreta, increta, or percreta). Placenta previa...
ocurs when the implanted placenta overlays the cervical os. Bleeding is due to partial separation of the placenta from the uterine wall. Uterine atony occurs when myometrial dysfunction prevents the uterine corpus from contracting, allowing continued bleeding at the placental site. Atony is more likely to occur with conditions that overdistend the uterus, such as polyhydramnios, multiparity, prolonged labor, induced labor, high pitocin usage during labor, precipitous labor, magnesium therapy, or intrauterine infection (chorioamnionitis).

Nonpregnant Patients

The pathophysiology of nonpregnant vaginal bleeding varies with age group. Children may present with foreign bodies, genital trauma, or severe vulvovaginitis causing mucosal breakdown and hemorrhage. Sexual abuse must always be considered. In adolescent girls and women, anovulatory uterine bleeding occurs when estrogen stimulates endometrium proliferation without the stabilizing effect of progesterone, causing spontaneous sloughing of the endometrium. Submucosal leiomyomas cause hemorrhage by disrupting the endometrial vascular supply and the ability of the uterus to contract to stop bleeding. Cervical and endometrial polyps have vascular pedicles and are prone to bleed.

### Differential Considerations

The differential diagnosis can be categorized by age of presentation and frequency of cause (Table 27-2). Primary coagulation disorders account for almost 20% of acute menorrhagia in adolescents. Von Willebrand’s disease is the most common; however, myeloproliferative disorders and immune thrombocytopenia are also possibilities. After immediate resuscitation and stabilization of unstable patients, pregnancy status is determined. Patients presenting with hemodynamic instability require intravenous access, fluid resuscitation, stabilization with blood components, and consultation with obstetrics/gynecology (or, less often, surgery). Concurrently, steps must be taken to prevent further vaginal bleeding. In hemodynamically unstable patients, surgical intervention is often necessary to control bleeding effectively. Ectopic pregnancy should be considered in all women of childbearing age who present with abdominal or pelvic complaints or with unexplained signs or symptoms of hypovolemia.

Nonuterine causes of vaginal bleeding must be included in the differential diagnosis, systematically addressed during the history taking and physical examination, and pursued with relevant investigations and consultations, if indicated. Potential sources of nonuterine bleeding include the cervix, vagina, lower urinary tract, and lower gastrointestinal tract. Cervical causes include carcinoma, polyps, condylomata, evasion of squamocolumnar junction associated with oral contraceptive use or pregnancy, trauma, and some infections. Vaginal sources of bleeding include carcinoma, sarcoma, adenosis, lacerations, infections, and retained foreign bodies. Lower urinary tract lesions, such as urethral faruncles and infected urethral diverticula, may also mimic vaginal bleeding.

### Pivotal Findings (Symptoms, Signs, and Laboratory)

#### Symptoms

The volume, duration, and timing of bleeding should be ascertained. The average tampon or pad absorbs 20 to 30 mL of...
vaginal effluent, although the number of pads or tampons used is unreliable because personal habits vary greatly among women. Amenorrhea may not indicate pregnancy, and bleeding during approximately the time of the last expected period does not exclude pregnancy. Bleeding during or after intercourse may indicate a cervical lesion and is more common in pregnancy because of increased blood flow to the cervix. Abdominal pain may indicate critical, emergent, or noncritical causes, depending on the severity of pain, bleeding, and hemodynamic state. During active labor, a history of previous cesarean section, cocaine abuse, or high doses of oxytocin or prostaglandins should raise the suspicion of uterine rupture. A history of trauma should be considered in an adolescent with bleeding, and sexual assault should be considered in an adult in whom abuse is present. In the pregnant patient, there is significant increased risk of maternal and fetal morbidity and mortality after blunt trauma, such as motor vehicle accident, interpersonal violence, or falls. Associated symptoms of nausea, breast tenderness, urinary frequency, and fatigue may indicate that the patient is pregnant. In the absence of pregnancy, vaginal discharge, pelvic pain, and fever may suggest pelvic inflammatory disease. Pelvic inflammatory disease is very rare during pregnancy.

Signs

A thorough evaluation includes recording and interpreting vital signs, abdominal and pelvic examinations, and, in the pregnant patient of sufficient gestational age, fetal heart tones and fundal height. Vaginal bleeding associated with hemodynamic shock alerts the clinician to ruptured ectopic pregnancy. Fetal heart tones that are diminished to less than 100 or that are absent in a gravid female may indicate fetal distress. Pelvic examination may reveal the source of bleeding; however, after the 20th week of gestation, ultrasound should precede pelvic examination to avoid disruption of a possible placenta previa. Bedside transabdominal ultrasound imaging may reveal free intraperitoneal fluid in an unstable patient, which should lead to immediate gynecologic or surgical evaluation.

Uterine size, measured from the symphysis pubis to the fundus, is the quickest means of roughly estimating gestational age. This distance in centimeters equals the gestational age in weeks (e.g., 24 cm = 24 weeks), which allows some early indication of fetal viability if delivery is necessary. Usually, 24 or 25 weeks is used as the cutoff point for fetal viability. As a rough guide, the fetus is potentially viable when the dome of the uterus extends beyond the umbilicus. Fetal heart tones can be detected by auscultation at 20 weeks of gestation or by Doppler probe at 10 to 14 weeks. If either the uterus is less than 24 cm in size or fetal heart tones are absent, the pregnancy is probably too early to be viable, and treatment is directed solely at the mother.

Ancillary Testing

In hemodynamically compromised patients, blood is obtained for hematocrit, platelet count, prothrombin time, partial thromboplastin time, ABO and Rh typing, and cross-matching of blood. Ultrasound is the imaging modality of choice for simultaneous assessment of the mother and the fetus. In the pregnant trauma patient, it is useful in the detection of major abdominal injury (sensitivity 80%, specificity 100%) and for establishing fetal well-being or demise, gestational age, and placental location. Computed tomography and magnetic resonance imaging are rarely indicated in the evaluation of vaginal bleeding, except in the case of pregnant trauma patients to diagnose potentially life-threatening injuries in those patients not proceeding directly to surgical intervention.

Qualitative tests in clinical use are typically reported as positive when the β-hCG concentration is 20 mIU/mL or higher in urine and 10 mIU/mL or higher in serum. At this level of detection, the false-negative rate for detection of pregnancy will not be more than 1% for urine and 0.5% or less for serum. In clinical use, the performance of urine qualitative testing has been found to be 95 to 100% sensitive and specific compared with serum testing. When a bedside urine test is negative and ectopic pregnancy is still being considered, a quantitative serum test should be performed. The sensitivity of quantitative serum testing for the diagnosis of pregnancy is virtually 100% when an assay capable of detecting 5 mIU/mL or more of β-hCG is used. The discriminatory level of serum β-hCG for ectopic pregnancy is 1500 to 2000 mIU/mL. Below this level, with no evidence of an intrauterine pregnancy (IUP) on transvaginal ultrasound, ectopic pregnancy as well as normal IUP are still possible. Above this level, ectopic pregnancy is diagnosed by the absence of an IUP on transvaginal ultrasound. In stable patients with minimal symptoms who are below the discriminatory level, serial quantitative β-hCG levels every 48 hours may distinguish ectopic pregnancy from IUP and spontaneous abortion in pregnancies less than 5 to 7 weeks of gestation. A system for close follow-up with gynecology is essential to an outpatient strategy for such patients. Additional testing such as progesterone level may help to distinguish normal verses abnormal pregnancy. A progesterone level of less than or equal to 5 ng/mL indicates a nonviable pregnancy, ectopic pregnancy, or IUP and excludes normal pregnancy with 100% sensitivity (Figs. 27-1 and 27-2).

EMPIRICAL MANAGEMENT

All patients who present in shock with a surgical abdomen or evidence of intra-abdominal free fluid should be resuscitated and promptly evaluated with immediate consideration of operative intervention in consultation with obstetrics/gynecology and surgery.

Pregnant Patients

If ectopic pregnancy is suspected and the serum or urine β-hCG is positive, and the patient is hemodynamically unstable, immediate surgical consultation is indicated. If bleeding presents with shock after the 20th week of pregnancy, stabilization is performed while obtaining a transabdominal ultrasound to evaluate the placenta (location in placenta previa and separation and hemorrhage in placenta abruptio). In the presence of vaginal bleeding in these patients, bimanual or speculum vaginal examination or transvaginal ultrasound should not be undertaken until placenta previa is excluded. High-grade third-trimester bleeding should prompt immediate obstetric consultation, even before diagnostic studies elucidate the possible cause. Vaginal delivery is the preferred management of third-trimester vaginal bleeding in the absence of placenta previa, but cesarean section is indicated if (1) fetal distress is present and vaginal delivery is not imminent, (2) there is severe abruption with a viable fetus, (3) life-threatening hemorrhage exists, or (4) the patient has failed a trial of labor.

Uterine rupture may present with excessive vaginal bleeding, uterine pain, and a change in abdominal contour. A soft horizontal lump often appears below a hard fundus, representing expanding hematoma and a retracting uterus, respectively. Emergent surgical delivery is indicated.

Urgent cesarean section is performed if excessive vaginal bleeding accompanies the rupture of membranes and the fetus...
shows signs of distress. Painless vaginal bleeding with rupture of membranes classically suggests vasa previa; it indicates fetal bleeding and requires emergent cesarean section. If after delivery of the fetus the placenta adheres abnormally and has difficulty separating, placenta accreta is likely present and may require urgent hysterectomy to prevent life-threatening hemorrhage. If available, interventional radiology for thromboembolization may be considered. Firm bimanual compression of the uterus or insertion and inflation of a Foley catheter with a 30-mL balloon may limit hemorrhage until surgery is arranged. Uterine atony often responds to vigorous uterine massage and intravenous oxytocin.13 Evidence for the administration of anti-D immunoglobulin (Rhogam) for the prevention of Rh seroconversion in pregnant women is limited. Nevertheless, it is recommended to administer anti-D immunoglobulin to Rh-negative women in all cases of documented first-trimester loss of established pregnancy, including threatened abortion, incomplete abortion, and ectopic pregnancy. One may consider administration of anti-D immunoglobulin in cases of minor trauma in Rh-negative pregnant women.14

Nonpregnant Patients
In nonpregnant patients, heavy vaginal bleeding may be under ovulatory control or related to anovulatory dysfunctional uterine bleeding. Nonsteroidal anti-inflammatory drugs are the mainstay of treatment for both conditions, although the exact mechanism of action is not clearly understood.15 In nonpregnant hemodynamically unstable patients, consider administering IV conjugated estrogen (Premarin) 25 mg and repeat doses if necessary until bleeding stops, usually within 1 to 5 hours. If bleeding continues after IV estrogen, insert a pediatric Foley catheter into the cervical os and inflate to tamponade the bleeding. Distend the balloon with saline until the bleeding stops. A larger balloon may be needed and this can be left in place for 12 to 24 hours. Hemodynamically stable patients can be referred for outpatient ultrasound and/or endometrial biopsy. All patients with abnormal uterine bleeding should receive close follow-up from a primary care physician or gynecologist. Outpatient treatment with oral contraceptives can arrest bleeding. Patients older than 35 years or with risk factors for endometrial cancer should have an endometrial
biopsy within one week of starting hormonal manipulation. A baseline hemoglobin/hematocrit is recommended. Finally, other medical causes, such as hypothyroidism, hemostasis disorders, or anticoagulant therapy, must be considered and appropriate outpatient consultation obtained.

### DISPOSITION

In a patient with postpartum uterine atony or coagulopathy, medical management is often sufficient. Obstetrics consultation is rarely indicated. In a preadolescent patient, abuse must be ruled out before the patient is discharged to her current environment. In a nonpregnant stable patient, malignancy always should be suspected, and additional inpatient or timely outpatient gynecologic workup is indicated. Laboratory studies such as thyroid function and prolactin levels may be helpful to the consultant or in the initial outpatient workup of dysfunctional uterine bleeding, but they are not required in the emergency department setting.

CHAPTER 28  Back Pain

Brian D. Mahoney,* Kevin G. Rodgers, and James B. Jones

PERSPECTIVE

Back pain is a common symptom causing patients to seek care in the emergency department (ED). It accounts for 2.3% of all physician visits,1 and 84% of the adult population have experienced low back pain in their lifetime.2 Forty-nine percent have suffered low back pain in the last 6 months2 and 26% in the last 3 months.1 Total costs of low back pain in the United States exceed $100 billion per year.3 Although mechanical or nonspecific low back is the most common cause, the differential diagnosis includes several life-threatening and disabling conditions (see Box 28-2). Developing a systematic approach that screens all the potential causes of back pain is the key to accurate clinical decision-making.

Epidemiology

Ninety-seven percent of patients presenting to a physician for evaluation of acute back pain, defined as lasting less than 6 weeks, are finally diagnosed with mechanical or nonspecific low back pain.4 Most will recover but many will have a recurrence within a year.5 For those with chronic back pain, defined as lasting longer than 3 months, persistence or a recurrence within 12 months is very common.5 About 1% of all patients with back pain have true sciatica.5 Back pain is the second most common cause of lost time in the workplace and an enormous source of health care expenditures and lost productivity.5,6

Before considering these common mechanical causes, several emergent diagnoses must be excluded, including aortic dissection, abdominal aortic aneurysm, cauda equina syndrome, epidural abscess, osteomyelitis, and tumor. The presence of “red flags” (Box 28-1) should prompt a more thorough examination of these possibilities. Visceral causes constitute about 2% of the diagnoses in patients presenting with back pain.7 Aortic dissection is a rare but catastrophic event, with mortality rates exceeding 90% if it is not diagnosed. Cauda equina syndrome (bilateral leg pain and weakness, urinary retention with overflow incontinence, fecal incontinence or decreased rectal tone, and “saddle anesthesia”) is a rare but disabling complication usually due to a large central herniated disk, and less often to tumor or infection. Epidural abscess and vertebral osteomyelitis comprise 0.01% of the diagnoses in patients complaining primarily of back pain.4 Spinal carcinoma is uncommon (0.7%) in the general population presenting with back pain.8 Of cancer patients, 80% who present with back pain have spinal metastases. Metastasis to bone is seen commonly in breast, lung, prostate, kidney, and thyroid carcinomas. Inflammatory arthritis is the diagnosis for 0.3% of patients presenting with back pain.4

Pathophysiology

The pathophysiology of back pain is diverse. Sources of pain include vascular, visceral, infectious, mechanical, and rheumatologic causes. Pain may originate in the spinal column, cord or root, or musculature or may be referred from thoracic or abdominal organs.

The gelatinous nucleus pulposus is surrounded by the tough anulus fibrosus. The anulus thins posteriorly, creating the opportunity for the nucleus pulposus to herniate. This varies from bulging, to protrusion, to extrusion, to sequestration. Ninety-five percent of herniations occur at the L4-5 and L5-S1 disk spaces, causing radicular pain in the L5 and S1 dermatomes.3 Sciatica radiates below the knees, causing focal motor and sensory loss. It worsens with bending, sitting, coughing, sneezing, and straining. Involvement of the L5 nerve root presents with decreased sensation in the first web space, weakness with extension of the great toe, and normal reflexes. An S1 radiculopathy is characterized by diminished sensation of the lateral small toe, impaired plantar flexion, and a decreased or absent ankle jerk. Disk bulging (52–81%) and anular tears with focal disk protrusion (32–67%) are commonly found in asymptomatic patients, whereas disk extrusion (0–18%) is not.8 Serial magnetic resonance imaging (MRI) studies show that two thirds of herniated disks regress or resolve over 6 months.9 The fact that so many patients with herniated disk improve over time, and the high incidence of findings in asymptomatic patients argues against early MRI or computed tomography (CT). This natural resolution of symptoms in disk disease is in contrast to spinal stenosis, which tends to remain the same or worsen over time.4

The spinal cord ends at L1 in the adult where it gives rise to the cauda equina. Compressive lesions above the cauda equina cause upper motor neurologic signs. Compression of the cauda equina leads to lower motor neurologic findings. The ligamentum flavum can thicken with age and along with degenerative changes contributes to spinal stenosis.

DIAGNOSTIC APPROACH

Differential Considerations

The emergency physician must first rule out life-threatening and disabling causes of back pain, including thoracic aortic dissection, ruptured abdominal aortic aneurysm, epidural

---

*I gratefully acknowledge the work of Kevin G. Rodgers and James B. Jones on this chapter in the last edition and who figure so prominently in this new edition.
abscess or compressive mass, spinal column injury with cord or root compression, and cauda equina syndrome. An accurate history and physical examination guides the investigation of possible more serious underlying pathologic process (Boxes 28-1 and 28-2). Laboratory and imaging are needed in some cases, but it is usually possible to rule out significant pathology without recourse to extensive testing.

**Rapid Assessment and Stabilization**

If the initial history and physical examination identify any suggestion of serious disease, rapid stabilization measures should ensue consistent with the cause of concern (Fig. 28-1). Management of aortic dissection, ruptured abdominal aortic aneurysm, and spinal cord and column injuries are covered in other chapters. If epidural abscess or cauda equina syndrome is suggested, emergent MRI and neurosurgical consultation should be obtained based on the results of the scan. For epidural abscess, blood cultures are obtained followed by intravenous (IV) administration of antibiotics against *Staphylococcus aureus*. For cauda equina syndrome, an urgent neurosurgical consultation is required. Although the evidence supporting steroid use is conflicting, dexamethasone is commonly used with the hope of decreasing compression from inflammation or to shrink tumor mass. For all patients with significant pain, including patients with “benign” causes for back pain, effective analgesia should be provided early in the evaluation.

**Pivotal Findings**

**History**

**History of Present Illness.** The history helps to localize pain to the most likely structure and mechanism. The following questions are useful in differentiating between mechanical and nonmechanical causes and will help guide appropriate management.

**Differential Considerations in Acute Low Back Pain**

**Emergent**

- Aortic dissection
- Cauda equina syndrome
- Epidural abscess or hematoma
- Meningitis
- Ruptured/expanding aortic aneurysm
- Spinal fracture or subluxation with cord or root impingement

**Urgent**

- Back pain with neurologic deficits
- Disk herniation causing neurologic compromise
- Malignancy
- Sciatica with motor nerve root compression
- Spinal fractures without cord impingement
- Spinal stenosis
- Transverse myelitis
- Vertebral osteomyelitis

**Common or Stable**

- Acute ligamentous injury
- Acute muscle strain
- Ankylosing spondylitis
- Degenerative joint disease
- Intervertebral disk disease without impingement
- Pathologic fracture without impingement
- Seropositive arthritis
- Spondylolysis

**Referred or Visceral**

- Cholecystitis
- Esophageal disease
- Nephrolithiasis
- Ovarian torsion, mass, or tumor
- Pancreatitis
- Peptic ulcer disease
- Pleural effusion
- Pneumonia
- Pulmonary embolism
- Pyelonephritis
- Retroperitoneal hemorrhage or mass

**Where is the pain?** The patient is asked to point with one finger to the one spot where it hurts the most. Does the pain radiate to the legs and, if so, specifically where in the legs? Does the pain conform to a specific dermatomal area? Radicular pain, particularly extending below the knee in a dermatomal distribution, implies nerve root involvement. Pain mainly in the paralumbar musculature without dermatomal radiculopathy implies nonspecific low back pain. Any associated chest or abdominal pain may indicate a possible visceral cause. Flank location implies a renal origin, and a higher location can be from the chest or pleura.

**When did the pain start?** The patient should describe in detail what he or she was doing when the pain started. Has there been a recent change in type or intensity of physical activity? Is there any past history of back pain, and what therapeutic modalities were used to treat it? If there is a history of back pain, is there any difference between present and past pain? Acute onset associated with a specific task suggests a mechanical cause. Sudden-onset, severe back pain suggests aortic dissection. Slow onset or onset unrelated to activity suggests a nonmechanical cause (e.g., tumor). Non-
mechanical pain may improve then recur, but the trend is progressive worsening.

Are there any aggravating or alleviating factors? Cough or Valsalva maneuver that aggravates the pain in general favors a mechanical cause and may point specifically to a herniated disk. Patients with back pain associated with tumors and infectious causes often present with nighttime pain and persistent pain unrelieved by rest and analgesics. Spinal stenosis presents with diffuse back pain, numbness, and tingling in one or both legs (pseudoclaudication). Symptoms are aggravated by ambulation (especially “downhill”) and relieved with spinal flexion, which increases spinal canal diameter, temporarily relieving the stenosis. Direct trauma may suggest contusion, strain or fracture, while deceleration may suggest aortic dissection.

Is there motor or sensory loss, bowel or bladder dysfunction? Back pain associated with progressive or severe neurologic symptoms, motor loss, or urinary retention or bowel incontinence requires MRI or CT, which may indicate the need for emergent decompression.

Is there other pertinent history? Other pertinent history should include work history, past and present (a history of repeated loading would suggest mechanical cause); fever (suggesting infectious cause); medications (anticoagulants associated with epidural hematomas, steroids associated with infection and compression fractures); hematuria (suggest nephrolithiasis or pyelonephritis); and pending litigation or worker’s compensation status (possible secondary gains).

Past Medical History. In addition to any history of back disorders, a thorough inquiry about any systemic disease is important. Ask if there is a history of (1) cancer (metastatic disease), (2) inflammatory disease, (3) IV drug abuse (diskitis), (4) arthropathies, (5) endocrinopathies (hyperparathyroidism), (6) bleeding disorders, (7) osteoporosis, or (8) sickle cell disease. Previous atherosclerotic or vascular disease suggests aortic disease; previous kidney stones or alcohol-related disease may suggest related disease. Knowledge of medications or other modalities used to treat present and past symptoms informs direct treatment decisions. Knowledge of current medications used by the patient gives clues about the presence of other systemic disease. The family history also is assessed. Diseases such as spondyloarthropathies (e.g., ankylosing spondylitis) have a familial component.

Physical Examination

Vital Signs. Vital signs are important because alterations may suggest a life-threatening process (e.g., hypotension and tachycardia with ruptured abdominal aortic aneurysm, hypertension with aortic dissection, fever with abscess, osteomyelitis, or diskitis).

Lower Back Inspection.

1. Observe the patient’s gait and movement in the examining room. Does the patient move cautiously, protecting himself or herself, or freely and appear to be in little pain?
2. Examine the patient while standing, searching for scoliosis (may be structural or secondary to muscle spasm), increase or decrease of lumbar lordosis or thoracic kyphosis (may predispose to mechanical pain), or pelvic obliquity (may indicate muscle spasm, leg-length discrepancy, or uncompensated scoliosis).
3. Assess the range of motion for the low back. Patients with significant mechanical pain usually flex without reversing the normal lumbar lordosis, and extension may aggravate facet causes or nerve root impingement.
4. Perform the palpation in an orderly fashion with the fingertips to localize the area of greatest tenderness (e.g., specific spinous process, paravertebral musculature).

Other Examinations, Including Neurologic Examination.

1. The neurologic assessment evaluates the asymmetry of reflexes (clinically, reflexes diminish with age, and uncovering asymmetry is key), dermatomal sensory loss, and focal muscle weakness (suggests nerve root impingement). If possible, motor testing of the legs is best done with the patient standing. Heel-walking and toe-walking indicate normal plantar and dorsiflexion strength, and a partial knee bend while bearing weight on one leg, then the other, indicate normal hip, buttock, and thigh muscle strength. A patient with a long history of back pain should be asked about previous motor, sensory, or reflex abnormality. The presence of clonus, hyper-reflexia, or upgoing toes (Babinski’s sign) indicate an upper motor neuron lesion.
2. A rectal examination can assess sphincter tone and anal wink. Testing for perianal sensation is necessary if there is any history of bowel or bladder dysfunction.

Figure 28-1. Rapid assessment of acute low back pain. AI, aortic insufficiency; UE, upper extremity.
3. A head-to-toe examination looking for signs of systemic disease should include cardiac and pulmonary auscultation; abdominal examination for tenderness, aneurysm, or masses; and palpation of peripheral pulses.

4. The hips are examined for a musculoskeletal or inflammatory focus other than the back.

**Straight Leg Raise.** The straight leg raise is the classic test for sciatic nerve root irritation. It is sensitive but not specific for disk stenosis.4 This test is often negative in patients with spinal stenosis. With the knee extended, the leg is elevated until pain is elicited. A positive result is pain radiating down the leg below the knee in a dermatomal distribution when the leg is elevated to less than 90° (not back, buttocks, or thigh pain). Pain referred to an affected leg (“crossover pain”) with straight leg raise of the unaffected leg is insensitive but highly specific for nerve root irritation. In a patient who may be malingering, the straight leg raise can be done with the patient sitting with the knees flexed at the side of the bed and then passively straightening the legs. If there is true nerve root irritation, results should be similar in the sitting and the supine positions.

**Ancillary Testing**

**Laboratory Tests.** For mechanical causes of back pain, laboratory studies are of little use. For nonmechanical causes, erythrocyte sedimentation rate and complete blood count may be useful if inflammatory disease is suggested, but are rarely of use in the ED. Urinalysis is helpful in possible cases of renal disease with referred back pain (nephrolithiasis, pyelonephritis, urinary tract infection).

**Imaging.** Although patient satisfaction is reportedly improved when imaging is performed,13 plain radiographs are not useful in uncomplicated mechanical low back pain of less than 6 weeks duration.12 If the patient has a history of trauma with bony tenderness or focal signs of trauma, neurologic deficit, cancer, unexplained weight loss, pain that persists at rest or at night, advanced age, osteoporosis, prolonged glucocorticoid use, or fever, plain radiographs may be helpful.15 Plain radiographs should not be obtained, however, if advanced imaging (e.g., CT, MRI) is planned. Most patients do not require radiographic evaluation while in the ED.14 Emergency MRI, CT, or myelogram (in order of preference) is indicated if an acute, significant neurologic deficit such as motor loss or cauda equina syndrome is present. For patients with acute back and radicular pain but no motor weakness, and for those with chronic low back pain without neurologic deficit, obtaining MRI and CT does not improve outcome.15-17 Eighty-four percent of patients with sciatica will recover without surgery.18 For patients in whom infection or tumor is suggested, MRI (or bone scan followed by MRI) is the diagnostic test of choice.19 The degree of neurologic impairment and patient stability dictates whether these tests are obtained on an emergent or urgent basis.

### DIFFERENTIAL DIAGNOSIS

After stabilization and assessment, the clinical findings aid in narrowing the differential diagnosis (Table 28-1). An algorithm

AV: arteriovenous; CBC: complete blood count; CT: computed tomography; GI: gastrointestinal; MRI: magnetic resonance imaging; SLE: systemic lupus erythematosus.
(see Fig. 28-1) that takes into account important differential considerations, such as abnormal vital signs, the presence of fever, and an abnormal neurologic examination, is a useful tool. After collecting this information the emergency physician should be able to answer two additional key questions. Does the patient need emergent, urgent, or more routine treatment? Does the patient need surgical or medical treatment? Young children for whom there is no clear explanation of their back pain warrant earlier and more extensive evaluation for infection and tumor.

**EMPIRICAL MANAGEMENT**

The initial empirical management of acute back pain depends on the presenting vital signs and the patient’s overall appearance. Figure 28-2 details the specific management considerations for treating unstable patients.20-26 For a stable patient, early effective pain management can be of significant value. The choice of analgesic is dictated by the patient’s and physician’s perception of the degree of pain. Physicians notoriously underestimate and undertreat pain, especially acute and chronic low back pain. If the pain is severe, IV opioids are the preferred analgesic and should be given in a titrated fashion. Frequent reassessment of the patient for an adequate response is required. After adequate response to the initial IV opioid, an oral agent can be administered in preparation for discharge. For patients with less acute symptoms, an oral opioid or a nonsteroidal anti-inflammatory drug (NSAID) is appropriate. NSAIDs are effective for short-term relief of acute low back pain but are not superior to acetaminophen.27 Their safety profiles must be considered in patients with acid peptic disease, renal insufficiency, diabetes, and liver pathology. NSAIDs are routinely used for chronic back pain, but evidence for their effectiveness is lacking.28 Muscle relaxants such as

![Figure 28-2.](image-url)
benzodiazepines and cyclobenzaprine (Flexeril) may be effective adjuncts for acute low back pain, but their significant adverse side effects require they be used with caution.29,30

For some patients, chronic recurrent mechanical back pain is a long-term issue. Such patients need support, and often a multidisciplinary approach to help manage their chronic pain or recurrent flare-ups. Management and follow-up require referral to primary care or a pain clinic. Tools that may be tried by their primary care or pain clinic may include lumbar supports,31,32 traction,33 acupuncture,34 spinal manipulative therapy,35 physical therapy or chiropractic therapy,36 back education,37 massage,38 exercise therapy,39 transcutaneous electrical nerve stimulation (TENS),40 heat therapy,41 epidural injection of methylprednisolone,42-44 and tricyclic or tetracyclic antidepressant therapy.45 ED treatment is directed to relief of their current exacerbation.

■ DISPOSITION

The disposition of patients with back pain depends on their diagnosis. Patients with one of the life-threatening or disabling causes require admission and further emergent treatment. Patients with acute cord compression from a fracture, disk protrusion, abscess, or hematoma require urgent neurosurgical evaluation.

Patients who are unable to walk or require IV analgesics for adequate pain control should be considered for admission to hospital or the ED observation unit. If pain can be controlled using oral analgesics, patients can be discharged with appropriate follow-up. Reassure the patient with acute mechanical back pain that the vast majority of patients eventually experience spontaneous relief of pain. Prescribe NSAIDs, supplemented with oral opioids for moderate to severe pain, and refer the patient for primary care. Oral opioids may be effective for short-term relief, but long-term efficacy is less clear and aberrant medication taking occurs in up to 24% of cases of chronic back pain.46,47 Repeat visits to the ED for chronic back pain can be a source of frustration for the physician and the patient. Patients frequently receive prescriptions for pain relief and referral for primary care but for many reasons do not complete this referral. For such a chronic, recurring, painful condition, repeat visits to the doctor are to be expected. Short-term oral opioids plus NSAIDs or acetaminophen may be what the patient needs. Rather than a consistent relationship with a primary care provider, repeat visits to the ED raise the possibility of drug seeking. For those patients, it may become necessary for the ED physician to prescribe simple analgesics such as NSAIDs instead of narcotics. Encourage patients to maintain activities as their pain allows, avoiding heavy lifting or twisting during the acute phase. Advise patients to avoid strict or prolonged bedrest as it is no more effective and may be worse than maintaining reasonable activities.48,49

PERSPECTIVE

Epidemiology

Cyanosis is a blue or purple appearance of the skin or mucous membranes. This clinical finding is secondary to inadequately oxygenated blood perfusing peripheral tissues or the presence of abnormal hemoglobin forms unable to bind oxygen or to supply adequate oxygen to end organs and tissues. Cyanosis is a relatively rare presenting chief complaint in the emergency department (ED) and is most commonly noted in patients with a hypoperfused state or known cardiopulmonary disease, including congenital heart disease. Although carbon monoxide poisoning and cyanide toxicity result in difficulty with hemoglobin oxygenation or tissue hypoxia, these entities typically do not present with the clinical finding of cyanosis and are discussed in other chapters.

Pathophysiology

Cyanosis is evident on physical examination when the absolute amount of desaturated (unoxgenated) hemoglobin in the circulating capillary blood (>4–5 g/dL in whole blood) is elevated. It is not a percent of desaturated total hemoglobin mass or a decreased amount of oxyhemoglobin. For this reason patients with a relatively low hemoglobin exhibit cyanosis at a much lower partial pressure of oxygen (PaO₂) and arterial oxygen saturation (SaO₂) than those with normal hemoglobin levels. Cyanosis is an insensitive indicator of tissue oxygenation. Its presence suggests hypoxia, but its absence does not exclude it.

Abnormal hemoglobin forms contribute significantly to cyanotic disease. Under normal conditions, red blood cells (RBCs) contain hemoglobin with iron in the reduced ferrous state (Fe²⁺). The iron molecule may be oxidized to the ferric state (Fe³⁺) to produce methemoglobin. This reaction impairs the ability of hemoglobin to transport oxygen to and carbon dioxide from the tissues. The oxygen dissociation curve is shifted to the left, resulting in tissue hypoxia and lactic acid production (Fig. 29-1). Methemoglobin normally accounts for less than 1% of total hemoglobin. Cyanosis results when greater than 10 to 15% of the total hemoglobin is methemoglobin (>1.5 g/dL) that has a dark purple-brown color, even when exposed to room air. Methemoglobin is reduced to ferrous hemoglobin primarily by nicotinamide adenine dinucleotide (NADH) cytochrome-b₅ reductase, an enzyme system present within RBCs. A secondary NADPH-dependant system uses glutathione production and glucose-6-phosphate dehydrogenase (G6PD) to reduce methemoglobin to hemoglobin. This secondary pathway normally plays a minor role, but is accelerated by methylene blue.

Primary methemoglobinemia is a congenital error of enzyme metabolism, with either diminished levels of NADH reductase or an abnormally functioning enzyme. Patients may present with cyanosis in a stable compensated state. Acquired methemoglobinemia occurs when methemoglobin production (hemoglobin oxidation) is accelerated beyond the capacity of NADH reductase activity. This usually occurs as a drug reaction. (See Box 29-1 for common causes.) Newborns are at risk for methemoglobinemia because their NADH reductase activity is relatively low.

DIAGNOSTIC APPROACH

Differential considerations for patients presenting with cyanosis are listed in Box 29-2.

Pivotal Findings

Symptoms

The onset, duration, and time of day of symptoms, and any previous episodes should be noted. Precipitating factors may include exposure to cold air or water, high altitude, or exercise in patients with a history of cardiopulmonary disease. Additional history should include known congenital heart disease or cardiopulmonary disease, hypercoagulable states, and any family history of cyanotic disease or hematologic illness. A history of home or occupational exposures to fumes or chemicals should be obtained, including aniline, azo dyes (pyridium), phenacetin, and nitrates. A drug history should be reviewed, including use of prescription and over-the-counter medications, health food supplements, and herbal or alternative preparations. The potential of pseudocyanosis resulting from exposure to dyes, heavy metals, or topically absorbed pigments should be explored.

In infants, congenital heart disease is suggested by difficulty feeding, sweating, lethargy, poor weight gain, or respiratory distress. Episodic cyanotic events, or “Tet spells,” may be seen in children with tetralogy of Fallot (ventricular septal defect, overriding aorta, pulmonary stenosis or atresia, and right ventricular hypertrophy with outlet obstruction). These patients present with cyanosis, tachypnea, and anxiety due to
Central cyanosis is often secondary to the shunting of venous unsaturated hemoglobin into the arterial circulation or the presence of abnormal hemoglobin. A bluish discoloration of the skin and mucous membranes is best seen on perioral skin, oral mucosa, or conjunctivae.

Peripheral cyanosis is secondary to vasoconstriction and slow flow of normally oxygenated hemoglobin in arterial blood, allowing for greater oxygen extraction by the tissues. Peripheral cyanosis affects capillary beds and typically is seen in the extremities and nail beds. Differential cyanosis may occur in either the upper or lower (or the right or the left) half of the body, with the remainder appearing well oxygenated. This form of cyanosis usually is seen in cases of cyanotic heart disease with multiple anomalies.

Vital signs should be obtained on all patients. Temperature is typically normal. Blood pressure and heart rate may be high, normal, or low depending on the underlying cause. Upper airway obstruction and other signs of respiratory insufficiency should be sought. Intermittent apnea in infants suggests central nervous system immaturity or a central lesion. Infants with cyanosis, increased respiratory depth, periodic apnea episodés, or diaphoresis with feeding may have congenital heart disease. Tachypnea (>60 breaths/min) in a newborn may indicate a pulmonary disorder, congenital heart disease, infection, a metabolic disorder, or central nervous system pathology.

General appearance and mental status should be evaluated. The head, eyes, ears, nose, and throat examination may reveal central cyanosis. Funduscopic examination may detect dilated tortuous veins and papilledema in patients with cyanotic congenital heart disease. Jugular venous distention may be seen on the neck examination in patients with pulmonary edema.

The chest examination may reveal crackles, wheezing, or inadequate ventilation. Heart sounds should be assessed for tachycardia, abnormal rhythm, or gallop, and the presence and quality of murmurs, especially in newborns. Central pulse strength should be noted. The abdomen should be examined for the presence of hepatosplenomegaly, a pulsatile mass, or abdominal bruit.

Extremity examination includes evaluation of nail beds for peripheral cyanosis, strength and symmetry of distal pulses,
Differential Diagnosis of Cyanosis

BOX 29-2

I. Peripheral cyanosis
   A. Low cardiac output states
      1. Shock
      2. Left ventricular failure
      3. Hypovolemia
   B. Environmental exposure (cold)
      1. Air or water
   C. Arterial occlusion
      1. Thrombosis
      2. Embolism
      3. Vasospasm (Raynaud’s phenomenon)
      4. Peripheral vascular disease
   D. Venous obstruction
   E. Redistribution of blood flow from extremities

II. Central cyanosis
   A. Decreased arterial oxygen saturation
      1. High altitude (>8000 ft)
      2. Impaired pulmonary function
         a. Hypoventilation
         b. Impaired oxygen diffusion
         c. Ventilation-perfusion mismatching
            (1) Pulmonary embolism
            (2) Acute respiratory distress syndrome
            (3) Pulmonary hypertension
   d. Respiratory compromise
      (1) Upper airway obstruction
      (2) Pneumonia
      (3) Diaphragmatic hernia
      (4) Tension pneumothorax
      (5) Polycythemia
   B. Anatomic shunts
      1. Pulmonary arteriovenous fistulae and intrapulmonary shunts
      2. Cerebral, hepatic, peripheral arteriovenous fistulae
      3. Cyanotic congenital heart disease
         a. Endocardial cushion defects
         b. Ventricular septal defects
         c. Coarctation of aorta
         d. Tetralogy of Fallot
         e. Total anomalous pulmonary venous drainage
      f. Hypoplastic left ventricle
   g. Pulmonary vein stenosis
   h. Tricuspid atresia and anomalies
   i. Premature closure of foramen ovale
   j. Dextrocardia
   k. Pulmonary stenosis of atrial septal defect
   l. Patent ductus arteriosus with reversed shunt
   C. Abnormal hemoglobin
      1. Methemoglobinemia
         a. Hereditary
         b. Acquired
      2. Sulphhemoglobinemia
      3. Mutant hemoglobin with low oxygen affinity (e.g., hemoglobin Kansas)

and capillary refill. Evidence of chronic vascular disease, such as hair loss and temperature difference, should be noted. Clubbing of the nails may occur due to increased soft tissue and expansion of the capillary beds (Fig. 29-2). Clubbing may be idiopathic or hereditary, but is usually the result of chronic hypoxemic states, such as cyanotic heart disease, infective endocarditis, pulmonary disease (chronic obstructive pulmonary disease, cystic fibrosis), and some gastrointestinal disorders (cirrhosis, Crohn’s disease, and regional enteritis). Thrombotic events should also be considered with findings of skin and nail bed hemorrhages or end-organ damage (eye, kidney).

A neurologic examination should be performed focusing on mental status, symmetry of motor and sensory function, and any gross deficit.

Laboratory and Ancillary Testing

The complete blood count should be checked to assess for polycythemia or anemia. Peripheral smear assesses RBC morphology and fragments, as well as white blood cell differential count.

Interpretation of pulse oximetry is problematic in the setting of cyanosis (see Chapter 3). Assessment of distal perfusion usually determines if poor circulation is a cause of low pulse oximetry. Pulse oximetry measures light absorbance of tissue at 660 nm (red reduced hemoglobin) and 940 nm (infrared oxyhemoglobin). The ratio of these two readings is the basis of the pulse oximetry calculation. Methemoglobin absorbs well at both wavelengths, resulting in a saturation approximation of 85%, regardless of the actual PaO₂ and SaO₂.

Arterial blood gas testing assesses SaO₂, often sampled when the patient is breathing room air (see Fig. 29-1). Co-oximetry measurements should be specifically ordered if carbon monoxide exposure or methemoglobinemia is suspected. Sulphhemoglobin is reported as methemoglobin on co-oximetry, so if sulphhemoglobinemia is possible, measured oxygen saturation should be specifically requested.

Imaging

A chest radiograph should be ordered to evaluate lung fields for consolidation, infiltrates, and increased vascularity or pulmonary edema. The cardiac silhouette and mediastinum may suggest congenital heart disease. In patients thought to have pulmonary embolism, imaging may include lower extremity venous Doppler ultrasound (if deep venous thrombosis...
symptoms are present), ventilation-perfusion scanning or computerized tomography pulmonary angiogram.

**Electrocardiogram and Echocardiogram**

An electrocardiogram should be performed on all patients with cyanosis to assess for arrhythmias and acute ischemic changes. Right-axis deviation or right ventricular hypertrophy may be seen with significant cardiopulmonary disease (e.g., cor pulmonale, acute pulmonary hypertension). An echocardiogram may be helpful in detecting septal defects in infants or valvular disease in infants and adults.

### DIFFERENTIAL ALGORITHMS

Figures 29-3 and 29-4 outline the differential diagnosis and treatment for peripheral and central cyanosis, respectively. After the initial assessment is completed, and the distribution of cyanosis is noted, the clinician should begin 100% oxygen therapy and follow steps to determine the cause of cyanosis. Clinical improvement with oxygen suggests diffusion impairment. Patients who do not respond to oxygen are more likely to have ventilation-perfusion ratio abnormalities, such as shunting from a consolidated pulmonary lobule, or congenital heart disease with right-to-left shunting. Cardiac size and silhouette on chest radiograph may provide a clue to the presence of congenital cardiac disease. If heart size is normal, impaired pulmonary function, pulmonary embolus, or other noncardiac causes should be considered. If no improvement occurs with 100% oxygen therapy, the patient’s respiratory status should be reassessed, and tension pneumothorax or upper airway obstruction considered. Pulmonary embolus should be considered and a ventilation-perfusion scan or spiral computed tomography pulmonary angiogram performed. If a patient exhibits no respiratory distress and remains resistant to oxygen therapy, cardiac shunting or abnormal hemoglobin forms should be considered and treated accordingly.

### Critical Diagnoses

Acute cardiovascular and respiratory compromise must be considered in a patient presenting with cyanosis and symptoms or signs of shock. The differential diagnosis for these critical presentations includes acute congestive heart failure, acute coronary syndromes, hypovolemic or cardiogenic shock, acute respiratory insufficiency or failure, massive pulmonary embolism, an exacerbation or decompensation in a patient with known congenital heart disease, or the first presentation of pediatric congenital heart disease. These patients require emergent treatment, critical therapeutic intervention, and admission to the intensive care unit.

---

**Figure 29-3.** An algorithmic approach to peripheral cyanosis. ABCs, airway, breathing, circulation; ABI, ankle brachial index; IV, intravenous.
Figure 29-4. An algorithmic approach to central cyanosis. ABCs, airway, breathing, circulation; ABG, arterial blood gas; AV, arteriovenous; CHF, congestive heart failure; CN, cyanide; CO, carbon monoxide; CTPA, computed tomography pulmonary angiography; CXR, chest radiograph; ECG, electrocardiogram; Echo, echocardiogram; G6PD, glucose-6-phosphate dehydrogenase; Hct, hematocrit; ICU, intensive care unit; IV, intravenous; LMWH, low-molecular-weight heparin; MetHgb, methemoglobin; PaO₂, partial pressure of arterial oxygen; PE, pulmonary embolus; prn, as needed; RA, room air; SaO₂, arterial oxygen saturation; SulfHgb, sulfhemoglobin; V/Q, ventilation-perfusion scan.

1 Patients with chronic cyanotic heart disease may not require ICU care or even admission. Disposition should be discussed with patient's cardiologist.

2 Cyanide and carbon monoxide toxicity do not present with cyanosis. If either of these is present, consider coexisting diagnosis.
Emergent Diagnoses

Methemoglobinemia is an infrequent cause of cyanosis, but should be considered in patients presenting without a history or physical findings suggestive of cardiovascular or pulmonary disease.

Sulfhemoglobinemia is a rare cause of cyanosis, most commonly occurring after exposure to hydrogen sulfide from organic sources, medications that are sulfonamide derivatives, or gastrointestinal sources (bacterial overgrowth). Strong consideration should be given to sulfhemoglobin toxicity in patients with cyanotic findings and methemoglobin on oximetry, but who do not improve with methylene blue treatment.

Polycythemia is defined as an elevated RBC mass due to one of three causes. Polycythemia vera is a disorder of bone marrow stem cells with increased RBC mass, cyanosis, and splenomegaly. Patients may present with hyperviscosity syndrome. Secondary polycythemia occurs with either an appropriate or inappropriate increase of erythropoietin, a physiologic response to chronic hypoxemia (<92% oxygen saturation), cyanotic congenital heart disease, cigarette smoking, or high altitude exposures. Relative polycythemia is an increased RBC mass, often due to dehydration or reduced plasma volumes.

Finally, vascular disease, such as Raynaud’s phenomenon, may present with a cyanotic appearance. Raynaud’s phenomenon occurs in 15% of the population and has a female predominance. Patients have an abnormal response to excessive cold or emotional stress and report vasoconstriction, profound cold sensitivity, and recurrent events of sharply demarcated pallor or cyanosis of the digits. Most commonly, the cutaneous arterial capillary beds of the fingers and toes are affected, but tongue, ear, and other distal areas are sometimes also affected.

EMPIRICAL MANAGEMENT

Administration of high-flow oxygen is the first therapy for patients with cyanosis. Any clinical improvement, or lack thereof, should be noted. At this point, consideration of abnormal hemoglobin and toxin-induced cyanosis is crucial because the administration of appropriate antidotes and systemic therapies may decrease morbidity and improve outcome.

Intravenous fluid resuscitation should be initiated in patients with hypovolemia. Treatment of congestive heart failure, arrhythmia, or poor cardiac output should occur as clinical conditions indicate. Cardiology consultation is recommended in patients thought to have congenital or ischemic heart disease. Although several specific treatments are discussed here, the cause of the cyanosis may be elusive, and hospitalization is required to determine it.

Specific Strategies

Methemoglobinemia and Sulfhemoglobinemia

If cutaneous exposure with an inciting agent occurred (i.e., aniline dyes), complete decontamination with soap and water is recommended. The staff should use appropriate protective equipment. Urgent treatment with oxygen and methylene blue (1–2 mg/kg IV over 5 minutes) is indicated for patients with symptomatic hypoxia (dysrhythmias, angina, respiratory distress, seizures, or coma) and methemoglobin levels greater than 30%. Sulfhemoglobinemia is suggested when the laboratory reports an elevated methemoglobin level and the patient does not respond to methylene blue. Treatment of sulfhemoglobinemia is supportive in addition to removing the causative agent.

Other Causes of Cyanosis

Acute therapy for patients with symptomatic hyperviscosity syndrome and secondary polycythemia includes phlebotomy and volume expansion with isotonic crystalloid. The goal of therapy is a normal hematocrit (45% in men and 42% in women). Long-term therapy is focused on the underlying cause, and patients may require referral to a hematologist.

Raynaud’s phenomena is treated with warming the affected digits and extremities. Systemic vasodilating agents (e.g., calcium channel blockers [nifedipine] or nitrates) may be useful in the acute setting. If there is no improvement of peripheral cyanosis with warming and administration of 100% oxygen, arterial insufficiency or occlusion may be present. In cases of critical limb ischemia, intravenous heparin should be considered in consultation with a vascular surgeon. Embolic sources, such as endocarditis and abdominal aortic aneurysms should be considered. Vascular bypass, intra-arterial thrombolysis, or stenting may be indicated.

Carbon monoxide and cyanide poisoning do not typically present with cyanosis and are covered elsewhere.

PATIENT DISPOSITION

Admission

All patients with a first episode of cyanosis or an uncertain cause require admission. Cardiology consultation and referral is recommended for children with a first episode of congestive heart failure and newly diagnosed or suggested congenital heart disease. Surgical consultation and intervention are indicated for acute arterial occlusion from embolic or thrombotic sources.

Discharge

Patients with peripheral cyanosis from vasospasm, asymptomatic methemoglobinemia less than 15%, and stable patients with primary pulmonary disease may be treated as outpatients, after several hours of monitoring in the ED. Unless the patient has a previous diagnosis of chronic cyanosis, follow-up must be arranged within 24 hours. Instructions should clearly state that if the cyanosis worsens, or if dyspnea, altered mentation, or chest pain occur after discharge, the patient must return immediately to the ED.
**Perspective**

**Epidemiology**

Sore throat is a frequent complaint among patients presenting to the emergency department (ED). The National Health Care Survey in 2001–2002 reported more than 2.4 million ED visits with complaints relating to the throat and acute pharyngitis diagnosed in more than 1.9 million patients. The chief complaint of sore throat is seen in every age group and has no sex predilection. Sore throat and other upper respiratory tract infections are some of the most common diseases for which care is sought and for which antibiotics are prescribed.

**Pathophysiology**

Sore throat results from irritation or inflammation of any anatomic surface within the oropharynx. The oropharynx is defined by the following borders: (1) posteriorly by the prevertebral fascia, (2) laterally by the buccinator muscle groups, (3) superiorly by the base of the skull, and (4) inferiorly by the vocal cords (Fig. 30-1). Pain may originate within the buccal mucosa, tongue, palatine tonsils, lingual tonsils, adenoids, soft palate, and posterior pharyngeal wall. In addition, pain may result from infection, inflammation, or invasive diseases of the potential spaces within and surrounding the oropharynx—the peritonsillar, retropharyngeal, sublingual, submental, lateral pharyngeal, parotid, buccal, and pretracheal spaces. Sore throat also occurs with inflammatory changes of the epiglottis, aryepiglottic folds, vocal cords, and subglottic region. Infectious diseases of dental structures and cervical nodes and the presence of middle ear fluid may cause sore throat through referred pain. The 9th and 10th cranial nerves provide sensory input from the oropharynx, larynx, middle ear, and external auditory canal. Many systemic diseases, including hepatitis, infectious mononucleosis, retroviral disease, and neutropenia, may also have sore throat as part of their symptom complex or initial presentation.

Sore throat commonly results from infections within the oropharynx, and the majority of these illnesses are self-limited. Table 30-1 lists common infectious and noninfectious causes of sore throat. Although the majority of infections are mild and not associated with serious complications, several infections may result in airway compromise, systemic disease, or sepsis.

Viruses cause the majority of cases of sore throat—up to 80% by some reports. Enterovirus infection accounts for the majority of sore throats in all age groups from late spring through autumn. Adenovirus, rhinovirus, parainfluenza virus, influenza virus, and respiratory syncytial virus predominate during winter months. Epstein-Barr virus (EBV), herpes simplex, and varicella-zoster virus have less seasonal predilection.

Acute pharyngitis due to bacterial infection is much less common than viral infection, and the cause can usually be discerned by a combination of clinical evaluation and rapid strep testing, because group A β-hemolytic streptococcus (GABHS) is the most common bacterial pathogen. Aerobes such as GABHS with anaerobes or anaerobes alone cause infection in the deeper planes of the pharynx and neck. GABHS is isolated as the offending pathogen in 10 to 15% of all patients with sore throat. The incidence of GABHS in school-age children with sore throat may reach 15 to 30%, and some studies have reported the incidence as high as 50%. GABHS is implicated in as few as 5% of adults with sore throat, but 47 to 73% of adults with pharyngitis are prescribed antibiotics. GABHS is most often isolated from patients between late winter and spring. GABHS infection may cause coinfection with other viral agents, but distinguishing acute infection from carrier state is difficult.

Fungal colonization and systemic infection with Candida albicans may occur throughout the oral cavity. Immunocompromised patients may present with severe infections or repeated infections. Recent antibiotic therapy, chemotherapy, and radiation therapy increase the risk for fungal colonization with Candida species.

Sore throat may be a manifestation of noninfectious systemic disease, trauma, tumor, or congenital anomaly. Additional systemic complaints or physical findings will often accompany these diseases.

**Diagnostic Approach**

**Differential Considerations**

The stable patient should receive a directed history and physical examination followed by judicious use of ancillary testing. Table 30-1 lists the possible causes of acute sore throat.

**Pivotal Findings**

**History**

Characteristic of Pain. Rapidly progressing symptoms, high fever, or severe pain suggest the possibility of invasive disease. A duration of several days accompanied by fever suggests deeper plane infection or systemic disease. Inflam-
mation or infection within Waldeyer’s ring is accompanied by pain localized to the oropharynx. Pain that radiates to the back of the neck or between the shoulder blades suggests prevertebral or retropharyngeal pathology (abscess or calcific tendinitis). Sore throat with radiation to the jaw or ear may be seen with dental abscess or deeper tissue plane infection.12

**Associated Complaints.** Odynophagia is almost universal, and many viral infections can cause a raspy dysphonia (laryngitis). The presence of severe pain or significant dysphagia, drooling, voice muffling (“hot potato” voice), or difficulty breathing, however, may indicate serious infection and potential for airway compromise. In the febrile patient, these symptoms suggest glossal abscess, severe infection of the lingual tonsils or palatine tonsils (peritonsillar cellulitis or abscess), epiglottitis, or Ludwig’s angina (submental or sublingual space infection).3,12

**Systemic Symptoms.** Prolonged fever (more than 5 to 7 days) may be seen in Kawasaki disease. Cough, myalgia, and arthralgia are seen with influenza A and B, parainfluenza, *Neisseria meningitidis*, and *Mycoplasma pneumoniae* infection. Hepatitis,
The patient's immunization status should be assessed, including (1) the presence of diabetes, (2) known immune disorders, or (3) recent chemotherapeutic or radiation therapy. Underlying alcoholism or malnutrition may place the patient at risk for more serious infections. Recent antibiotic use may indicate the presence of resistant organisms or atypical pathogens.

**Physical Examination**

Assessing for airway compromise or potential airway compromise is the critical first step in the approach to the patient with sore throat (Fig. 30-2). Rapid assessment of the patient can be accomplished by observing the patient's posture, color, level of consciousness, and phonation. Observation alone is especially important in the pediatric patient with potential airway compromise because attempts at a more thorough physical examination may result in agitation and progression to complete airway obstruction. The presence of air hunger, stridor, drooling, or toxic appearance may indicate pending airway obstruction. A complete ear, nose, and throat (ENT) and general examination will help narrow the differential diagnosis (Table 30-2).

A reduced functional caliber of the airway may occur acutely, subacutely, or insidiously, depending on the cause of the disease process. Pending airway loss leads to air-preserving posturing especially in children. Infants unable to sit without support choose the lateral decubitus position with the neck hyperextended when partial obstruction occurs. Children capable of sitting may support their heads with their hands. Airway obstruction in an older child is typically associated with fixed upright posturing. The patient has forced flexion at the waist and maintains the neck flexed and the head extended with an open mouth. Alternatively, patients may assume tripod posturing, in which additional support is gained by hands held on a surface.

**Ancillary Testing**

Laboratory procedures, other than rapid group A strep testing or throat culture, generally are not necessary to develop a working diagnosis of viral pharyngitis or GABHS pharyngitis (Table 30-3). Use of the Centor criteria, with or without rapid antigen detection test or culture, is a rational but not universally accepted approach. Patients with a score of 0 or 1 do not require treatment or additional testing. The goal is to decrease the cost of additional testing and decrease the inappropriate use of antibiotics while still treating those with GABHS to prevent suppurative and nonsuppurative complications.

A complete blood count is rarely helpful but may be used, along with serologic test for EBV, for the patient with a compatible presentation—severe sore throat, fever, and lymphadenopathy. Hematologic findings of leukocytosis, relative and absolute lymphocyte predominance, and the presence of atypical lymphocytes constituting more than 10% of the total leukocyte count suggest EBV. A serologic test such as the heterophile antibody screen (Monospot) may provide evidence of primary EBV infection. Patients with a negative serologic test but with compatible symptom complex should be retested a week later because heterophile antibodies may not be present in the first week in 10% of patients. In addition, CMV, acute retroviral illness, herpes simplex virus, and human herpes 6 viral infections should be considered.

A lateral portable upright neck radiograph may be used in the pediatric patient to narrow the differential diagnosis of infectious conditions associated with potential airway obstruction. The lateral neck film may demonstrate swelling in the prevertebral soft tissue in a patient with a retropharyngeal abscess (RPA). Plain radiographic imaging is rarely warranted in the adult patient with an acute sore throat. The adult with severe symptoms should be considered for direct nasopharyngoscopy to search for epiglottitis. Use of the H. influenza b vaccine in children has resulted in a dramatic decrease in the incidence of epiglottitis, but the incidence in adults has not changed. Ultrasonography may be a useful tool in the diagnosis and treatment of some deep space infections. The advantages of ultrasound are as follows: (1) It can be used at the bedside, (2) it can be used to guide incision and drainage

---

**Differential Diagnosis**

Table 30-1 lists the infectious and noninfectious causes of sore throat.

**Empirical Management**

The management of the patient presenting with a sore throat begins with a rapid assessment for potential airway compromise (Figs. 30-2 and 30-3). If the patient is in extremis, immediate airway control is obviously necessary. If the airway is patent and ventilation is adequate, diagnostic and therapeutic efforts may simultaneously commence. Infections within the parotid, buccal, parapharyngeal, submental, and sublingual spaces create masses that are readily apparent. The purulent material rapidly expands the tissues but rarely occludes the airway. A thorough head and neck examination accompanied by fiberoptic nasopharyngoscopy, ultrasonography, or CT scan may be necessary to identify the severity and extent of the process. Needle aspiration of a PTA can be both diagnostic and therapeutic. Intravenous antibiotics are administered to treat mixed infection with aerobic and anaerobic organisms. ENT consultation is often necessary for definitive management of PTA, RPA, and other infectious or mass lesions, and early consultation is often warranted.

The patient who is febrile and appears toxic, is in respiratory distress, has an abnormal voice or prefers not to speak, or is drooling through a persistently open mouth may require emergent airway management before any other diagnostic...
maneuvers are attempted due to impending airway compromise. If time permits, immediate transfer to the operating room may be warranted, with ENT and anesthesiology consultation. This requires that the operating room be ready to receive the patient and the patient be accompanied by a physician or surgeon capable of surgical cricothyrotomy. If the patient cannot be transported, then fiberoptic intubation (nasal or oral) is the preferred route, with light sedation and topical anesthesia (see Chapter 1). Equipment for cricothyrotomy should be readily available because instrumentation can lead to airway obstruction or laryngospasm. After the airway is secured, the infected surface and secretions can be swabbed for culture; tissue aspiration and blood culture specimens can be submitted for culturing. Broad-spectrum parenteral antibiotics are begun for mixed aerobic and anaerobic infection, and the patient should be admitted to the intensive care unit.

If the febrile patient does not have evidence of airway compromise but has vocal changes (e.g., muffled or “hot potato” voice), epiglottitis, peritonsillar cellulitis, or abscess may be present. If examination of the oropharynx does not identify the offending condition, then fiberoptic examination of the upper airway for epiglottitis is indicated. ENT need not be consulted for peritonsillar cellulitis or uvulitis. ENT may be consulted for peritonsillar abscess, even after needle aspiration, for incision and drainage. Intravenous antibiotics are provided to cover *Streptococcus pyogenes*, non-group A streptococci, and *Staphylococcus aureus*. The patient may require admission for further care if he or she has severe symptoms or is unable to tolerate liquids by mouth.

In the patient with a sore throat who has no evidence of airway compromise, the pain may be a problem within the oropharynx, referred from another location, or part of a systemic illness. Further workup may continue in the ED or on an outpatient basis. The patient with presumed or proven GABHS should be treated with antibiotics. Penicillin remains the drug of choice. Details of treatment are provided in Chapter 73.

Hemoptysis

Calvin A. Brown III

PERSPECTIVE
Epidemiology
Hemoptysis is defined as the expectoration of blood from the respiratory tract that originates below the vocal cords. Most cases are mild and consist of blood-tinged sputum or minute amounts of frank blood. The most common cause of small-volume hemoptysis is bronchitis. Rarely, hemoptysis is accompanied by massive blood loss, generally accepted as 100 to 600 mL of blood loss in any 24-hour period. In addition to manifesting as hemoptysis, endobronchial bleeding may impair alveolar oxygen exchange and cause significant morbidity and mortality. Rapid blood loss can also result in hemodynamic instability and shock.

Although hemoptysis is a common complaint in emergency populations, only 1 to 5% of hemoptysis patients have massive or life-threatening hemorrhage, with mortality rates approaching 80%. Large, contemporary series of patients with massive hemoptysis are lacking. Most etiologic data originate from small, often rural studies where tuberculosis (TB) and bronchiectasis are responsible for the vast majority of cases. In developed nations, cancer, cystic fibrosis, arteriovenous malformations, and postprocedural complications play a more prominent role. Pediatric hemoptysis is rare but can be caused by infection, congenital heart disease, cystic fibrosis, or bleeding from a preexisting tracheostomy.

Pathophysiology
Trace hemoptysis typically originates from tracheobronchial capillaries that become disrupted with vigorous coughing or minor bronchial infections. Massive hemoptysis almost exclusively involves one of the two sets of vessels that constitute the lung's dual blood supply. Bronchial arteries, direct branches from the thoracic aorta, are responsible for supplying oxygenated blood to lung parenchyma. Disruption of these vessels from arteritis, trauma, or bronchiectasis or erosion from an adjacent malignancy can result in sudden and profound hemorrhage. Although small in caliber, the bronchial circulation is a high-pressure system and the culprit in nearly 90% of the cases of massive hemoptysis requiring embolization. Pulmonary arteries, although transmitting large volumes of blood, are at much lower pressure and, unless affected at a very central location, are less likely to cause massive hemoptysis.

Nearly all causes of hemoptysis have a common mechanism—vascular disruption within the trachea, bronchi, small-caliber airways, or lung parenchyma. Modes of vessel injury include acute and chronic inflammation (from bronchitis and arteritis), local infection (especially lung abscesses, TB, and aspergillosis), trauma, invasion from a growing tumor, infarction following a pulmonary embolus and fistula formation (specifically aortobronchial fistulae).

Bronchiectasis, a chronic necrotizing infection resulting in bronchial wall inflammation and dilation, is one of the most common causes of massive hemoptysis. As tissue destruction and remodeling continue, rupture of nearby bronchial vessels results in bleeding. Bronchiectasis can complicate chronic airway obstruction, necrotizing pneumonia, TB, or cystic fibrosis. Broncholithiasis, the formation of calcified endobronchial lesions following a wide array of granulomatous infections, is an uncommon problem with a propensity to erode nearby vessels. Hemorrhage control often requires surgical intervention.

Iatrogenic hemoptysis may complicate 2 to 10% of all endobronchial procedures, especially percutaneous lung biopsies. Additionally, bleeding can be exacerbated by coagulopathy and thrombocytopenia. An uncommon cause includes ectopic endometrial tissue within the lung that can result in monthly catamenial episodes of hemoptysis. Diffuse alveolar hemorrhage can be seen with autoimmune vasculitides such as Wegener's granulomatosis, systemic lupus erythematosus, and Goodpasture's syndrome. Still others include pulmonary hereditary telangiectasias and hydatiform infections.

DIAGNOSTIC APPROACH
Differential Considerations

When a patient presents with apparent hemoptysis, two other potential sources of bleeding should be investigated. Nasal, oral, or hypopharyngeal bleeding sometimes inadvertently contaminates the tracheobronchial tree and can mimic true hemoptysis. The clinician should closely inspect the nasopharynx and oral cavity to exclude this possibility. Differentiating hemoptysis from a gastric or proximal duodenal source of bleeding is the principle diagnostic dilemma, since further evaluation and management follow divergent pathways. Usually, this can be done by the patient and physician discriminating coughing from vomiting. In unclear cases, inspection and pH testing may help to distinguish gastrointestinal from tracheobronchial hemorrhage. Unless an active, brisk upper GI hemorrhage is present, the acidification of blood in the stomach results in fragmentation and

223
darkening of its color. This produces specks of brown or black material often referred to as “coffee-grounds” emesis. Pulmonary blood appears bright red or as slightly darker clots and is alkaline.

**Rapid Assessment and Stabilization**

Although hemodynamic instability can occur as a result of hemorrhage, the most lethal sequela of massive hemoptysis is hypoxia resulting from the ventilation-perfusion mismatch that occurs as small airways and alveoli are submerged with blood. The clinician should consider the standard indications for emergency airway management in such cases.

As a mitigating maneuver in patients with a known lateralizing source of bleeding, the “lung down” position can be employed in which the patient is positioned so the bleeding lung is more dependent. This position can promote continued protection and ventilation of the unaffected lung and improve oxygenation. Large-bore (8.0) endotracheal tubes should be used to facilitate emergent fiberoptic bronchoscopy. In selected cases of confirmed left-sided bleeding, a single-lumen right-mainstem intubation can be successfully performed by advancing the tube in either the neutral position or by using a 90° rotational technique. Left-mainstem intubations are more difficult and should be attempted with caution.

The use of double-lumen endotracheal tubes for lung isolation should be reserved for dire circumstances and usually requires an experienced anesthetist. The correct positioning of blindly placed double-lumen tubes is difficult and requires confirmation by auscultation and fiberoptic bronchoscopy, both of which have severely impaired accuracy in massive hemoptysis. Complications of double-lumen tubes include unilateral and bilateral pneumothorax, pneumomediastinum, carinal rupture, lobar collapse, and tube malposition.

**Pivotal Findings**

**History**

Although patient reports of bleeding severity are historically inaccurate, a rough estimate of the rate, volume, and appearance of expectorated blood should be obtained.

Any history of parenchymal pulmonary disorders should be obtained, including the presence of bronchiectasis, recurrent pneumonia, chronic obstructive pulmonary disease, bronchitis, TB, and fungal infection. Inflammatory disorders that secondarily involve the lungs or pulmonary vasculature include Wegener’s granulomatosis, Goodpasture’s syndrome, and systemic lupus erythematosus. Risk factors for platelet dysfunction, thrombocytopenia, and coagulopathy may be present. Hypercoagulable states can contribute to deep venous thrombi and pulmonary embolism.

The presence of primary or metastatic cancer can cause hemoptysis by erosion into pulmonary and bronchial vessels. Recent percutaneous or transbronchial procedures can cause immediate or delayed postprocedural bleeding, and any recent history of trauma should also be noted. A pertinent travel history to areas endemic with TB or pulmonary paragonimiasis should be obtained.

**Physical Examination**

After a primary survey and stabilization, a targeted examination may suggest the location and etiology of bleeding, but does so in less than 50% of cases. Focal adventitious breath sounds may indicate pneumonia or pulmonary abscess. A new heart murmur, especially in a febrile patient, might reflect endocarditis causing septic pulmonary emboli. Symptoms and signs of deep venous thrombosis should suggest pulmonary embolism. Ecchymoses and petechiae can indicate coagulopathy and thrombocytopenia, respectively.

**Ancillary Testing**

Initial laboratory studies include a complete blood count, coagulation tests, and a type and screen or crossmatch. Renal function tests should be obtained if vasculitis is suggested or contrast computed tomography (CT) is planned. Plain chest radiography should be ordered, although its sensitivity is marginal. A prospective study of 184 consecutive patients with varying degrees of hemoptysis reveals that more than 40% of patients with a normal chest radiograph have a positive chest CT.

In patients with massive hemoptysis, plain films may localize the site of hemorrhage in as many as 80% of patients. High-resolution multidetector CT of the chest is the principle diagnostic test for investigating both bronchial and nonbronchial arterial causes of massive hemoptysis. CT is diagnostically comparable, yet less invasive, than conventional angiography, which is now done primarily as a combined diagnostic-therapeutic modality. A chest CT should be obtained in the high risk patient (smokers, oncology patients) or in any patient with moderate to severe bleeding even if the initial chest radiography is normal. CT localization of hemorrhage can expedite bronchoscopic evaluation or guide subsequent interventional procedures.

**DIFFERENTIAL DIAGNOSIS**

Potential causes of hemoptysis vary and include systemic illnesses as well as pulmonary parenchymal disease. Box 31-1 includes the most common causes.

**MANAGEMENT**

Since the advent of high-resolution CT, radiologic evaluation has had an integral role in the evaluation and treatment of patients with hemoptysis. The challenge to the emergency physician is to rapidly assess the need for airway control prior to hemodynamic stabilization. Unless the initial chest radiograph is diagnostic or the patient is hemodynamically unstable, a chest CT should be obtained in most cases. Further management strategy should be developed in conjunction with pulmonary and thoracic surgery consultants, guided by the CT results (Fig. 31-1).

**Bronchoscopy**

Early bronchoscopy facilitates both localization of bleeding and therapeutic intervention. Balloon and topical hemostatic tamponade, thermocoagulation, and injection of vasoactive agents can all control arterial bleeding. Optimal timing for bronchoscopy remains conjectural. Stable patients with mild to moderate bleeding may benefit from early bronchoscopy. In unstable patients or those with brisk hemorrhaging, bronchoscopy sometimes can facilitate airway management, but is less likely to control bleeding.

Chest CT is as diagnostically accurate as bronchoscopy in locating peripheral vessels not accessible by a flexible bronchoscope. Chest CT is used to identify the bleeding site and to determine whether angiography is indicated. There may be little benefit to bronchoscopy prior to interventional angiography if a CT scan has accurately identified a bleeding source.
and can be discharged with follow-up. High risk patients with minor hemoptysis and all patients with moderate or large amounts of hemoptysis should undergo plain chest radiography followed by emergent chest CT. Brief hospitalization or admission to an observation unit for bronchoscopy should be considered. All patients with massive hemoptysis require admission to an intensive care unit and expedited multidisciplinary treatment involving the emergency physician, pulmonologist, and thoracic surgeon.
CHAPTER 32  Red and Painful Eye

Joshua L. Wright and John M. Wightman

■ PERSPECTIVE

Epidemiology and Pathophysiology

Most eye complaints are not immediately sight-threatening and can be managed by an emergency physician. Nontraumatic diseases, such as glaucoma and peripheral vascular disease leading to retinal ischemia, are more common with advancing age. Ocular injuries are the leading cause of visual impairment and blindness in the United States. More patients with postoperative complications can be expected to present to the emergency department as more vision correction surgeries are performed.

The external and internal anatomy of the eye is depicted in Figure 32-1A and B. The globe has a complex layer of blood vessels in the conjunctiva, sclera, and retina. Redness reflects vascular dilation and may occur with processes that produce inflammation of the eye or surrounding tissues. Eye pain may originate from the cornea, conjunctiva, iris, or vasculature. Each is sensitive to processes causing irritation or inflammation.

■ DIAGNOSTIC APPROACH

Rapid and accurate triage is the most critical consideration in the approach to the red and painful eye. The first question should be, “Did anything get in your eye?” If so, the second question should be, “What do you think it is?” This helps separate trauma from nontrauma, but, more importantly, seeks to identify quickly eyes that may have been exposed to a caustic substance. Patients exposed to caustic materials require rapid decontamination to prevent permanent loss of visual acuity.

Differential Considerations

Diagnoses are classically divided into traumatic and nontraumatic. Traumatic pain and redness can be caused by caustic fluids and solid materials, low-velocity contact with a host of materials that can fall or be rubbed into the eye, higher velocity blunt-force impacts to the orbit or globe, or potentially penetrating injuries. Causes of nontraumatic pain and redness require a more detailed history, including contact lens use and questions directed toward determining the likelihood of systemic illnesses.

Pivotal Findings

Measurement of the patient’s best corrected visual acuity (i.e., with glasses on, if available) with each eye individually and with both eyes provides vital information when evaluating eye complaints. Only a few situations preclude early and accurate visual acuity testing. Eyes exposed to caustic materials should be decontaminated as soon as possible. Patients with sudden and complete visual loss in one eye require prompt funduscopic examination to determine the possibility of acute central retinal artery occlusion. This condition is readily apparent as a diffusely pale retina with indistinct or unseen retinal arteries (Fig. 32-2).

Other pivotal findings, which are more likely to be associated with a serious diagnosis, in patients with a red or painful eye are listed in Box 32-1.

History

Chief complaints of pain can be manifestations of a variety of sensations. When carefully questioned, some patients may differentiate between itching, burning, dull pain, sharp pain, and perception of a foreign body. Itching tends to be more often due to blepharitis, conjunctivitis, or dry eye syndrome. Burning is associated with these conditions and with other mostly extraocular problems such as irritation of a pterygium or pinguecula, episcleritis, or limbic keratoconjunctivitis. Dull pain may be a manifestation of increased intraocular pressure (IOP) or referred from an extraorbital process such as sinusitis, migraine headache, or temporal arteritis. Sharp pain generally results from abnormalities of the anterior eye, such as keratitis, uveitis, and acute angle-closure glaucoma. A foreign body sensation is more typical of corneal irritation or inflammation.

A chief complaint of redness commonly results from palpebral or limbal injection of the conjunctiva. However, free blood can be noted behind the bulbar conjunctiva (i.e., subconjunctival hemorrhage) or in the anterior chamber (i.e., hyphema). Both of these can be spontaneous or post-traumatic. Spontaneous subconjunctival hemorrhages may follow coughing or straining or may be due to systemic hypertension. Often, it occurs without any identifiable precipitating incident and is simply noticed by the patient when looking in the mirror. Spontaneous subconjunctival hemorrhage is painless, and the presence of pain raises concern for a more serious cause of the hemorrhage, such as direct globe injury. Hyphema of
Figure 32-1. External (A) and internal (B) anatomy. (From Ragge NK, Easty DL: Immediate Eye Care. St. Louis, Mosby-Year Book, 1990.)

Figure 32-2. Key funduscopic findings in acute central retinal artery occlusion include general pallor of the retina (except for a characteristic cherry-red spot where the perfused choroid shows through the thinner fovea) and attenuation of retinal arteries (possibly with retinal veins preserved as in the photograph). (From Kaiser PK, Friedman NJ, Pineda R, II: The Massachusetts Eye and Ear Infirmary Illustrated Manual of Ophthalmology, 2nd ed. Philadelphia, WB Saunders, 2004, p 297.)

**BOX 32-1**  
**PIVOTAL FINDINGS MORE LIKELY ASSOCIATED WITH A SERIOUS DIAGNOSIS IN PATIENTS WITH A RED OR PAINFUL EYE**

- Severe ocular pain
- Persistently blurred vision
- Proptosis
- Reduced ocular light reflection
- Corneal epithelial defect or opacity
- Limbal injection (i.e., ciliary flush)
- Pupil unreactive to a direct light stimulus
- Wearer of soft contact lenses
- Neonate
- Immunocompromised host
- Worsening signs after 3 days of pharmacologic treatment

sufficient size to be noted by the patient or bystander usually arises with pain and blurred vision.

Other subjective findings may be transient and detected only by history. The patient may relate lid swelling, tearing, discharge, crusting, or sensitivity to light. Lid swelling can be caused by inflammatory and noninflammatory processes. Concurrent erythema of the lid favors the former. In the absence of trauma or other external irritant (e.g., contact dermatitis), inflammatory processes include primary lid problems such as hordeolum (i.e., stye) or blepharitis as well as extension from concomitant conjunctivitis or cellulitis in orbital or peribulbar structures. When pain is present, tearing is usually secondary. Discharge and crusting are most commonly associated with conjunctivitis, whether allergic, viral, or bacterial. Blepharitis, dacryocystitis, and canalicularis are other inflammatory processes that may create a discharge and subsequent crusting. Other eye status review questions include the following:

- Are contact lenses used? If so, what type, how are they cleaned, and how old are the lenses? Has there been a change in the pattern of use (especially increased use)? Were the lenses worn for a particularly long period recently? Are there problems with the lenses drying out? Does insertion of the lenses worsen or relieve the symptoms?
- Are glasses worn? If so, when was the last assessment for adequate refraction?
- Has previous eye surgery or injury occurred?
- What is the patient’s usual state of health?
- What medications are being taken? Are there any allergies, including environmental allergies?

### Physical Examination

A complete eye examination usually includes eight components, although many patients require only a limited or directed eye examination, depending on the presentation. The mnemonic VVEEPP (pronounced “veep”) plus slit-lamp and funduscopic examinations represent these components (Box 32-2). Slit-lamp examination is recommended for any complaint involving trauma and for any medical presentation involving foreign body sensation or alteration of vision.

**BOX 32-2  COMPLETE EYE EXAMINATION**

- Visual acuity (best possible using correction)
- Visual fields (tested by confrontation)
- External examination
  - Globe position in orbit
  - Conjugate gaze
  - Periorbital soft tissues, bones, and sensation
  - Extraocular muscle movement
- Pupillary examination (absolute and relative)
- Pressure determination (tonometry)
- Slit-lamp examination
  - Lids and lashes
  - Conjunctiva and sclera
  - Cornea (with fluorescein in some cases)
  - Anterior chamber
  - Iris
  - Lens
- Funduscopic examination

### Visual Acuity

The initial determination of a patient’s visual acuity provides a baseline from which deterioration or improvement may be followed. It is also predictive of functional outcome after ocular trauma. Visual acuity is quantitatively assessed by use of a Snellen chart test at a distance of 20 feet (6 m) or a Rosenbaum chart at a distance of 14 inches. Young patients who cannot yet read letters and numbers should be tested with an Allen chart that depicts easily recognizable shapes. Each eye is tested separately with the opposite eye carefully covered. Patients who present without their prescribed corrective lenses may be evaluated by having them view the chart through a pinhole eye cover, which negates most refractive errors in vision.

If the patient cannot distinguish letters or shapes on a chart, visual acuity must be determined qualitatively. Any printed material suffices. The result may be recorded as, for example, “patient able to read newsprint at 3 feet.” If this is not possible, visual acuity is recorded as:

- Unable/able to count fingers (CF)
- Unable/able to perceive hand motion (HM)
- Unable/able to perceive light (LP)

### Visual Field Testing

Confrontation is the most common method of testing visual fields in the emergency department. Detection of a scotoma usually represents a retinal problem. However, glaucoma may cause scotomata that can be crescent-shaped, involve just the binasal visual fields, or affect all peripheral vision. Hemi- or quadrantanopia is more commonly a problem of the neural pathways to the brain.

### External Examination

Gross abnormalities are assessed by a visual inspection of both eyes simultaneously. Findings may be more apparent if compared with the opposite side. Fractures of facial bones are associated with ocular injuries, some of which require immediate intervention by an ophthalmologist.

Globe position is part of the external examination. Subtle exophthalmos and enophthalmos are rare, and are best detected by looking inferriorly, tangentially across the forehead, from over the patient’s scalp. Exophthalmos may have traumatic or nontraumatic causes, but is due to increased pressure or a space-occupying lesion within the orbit, which may manifest as pain. Medical causes include cellulitis or intraorbital or lacrimal tumors. Hyperthyroidism may cause enlargement of extraocular muscles. The most important cause of exophthalmos in the emergency department is retrobulbar hematoma, a condition characterized by hemorrhage within the bony orbit, behind the globe. Orbital compartment syndrome pushes the globe forward, stretching the optic nerve and retinal artery and increasing IOP. The resulting microvascular ischemia is sight-threatening if sufficiently severe and persistent. Orbital emphysema and inflammation caused by a retained foreign body behind the eye are other causes of exophthalmos. The discovery of exophthalmos should prompt ocular tonometry measurements to determine the urgency of intervention. Trauma, particularly penetrating globe injury with extrusion
of vitreous, can cause the globe to recede into the orbit, but the most common cause of enophthalmos is actually pseudoenophthalmos when the contralateral globe is proptotic.

Inspection also involves examination of the upper and lower palpebral sulci for foreign bodies or other abnormalities. The lower sulcus is easily viewed after manual retraction of the lower lid toward the cheek and having the patient gaze upward. The upper sulcus is inspected by pulling its lashes directly forward and looking under the lid with white light. The lid can then be everted by pressing a cotton-tipped applicator in the external lid crease and folding the lid margin over the applicator.

**Extraocular Muscle Function**

Limitation of ocular movement in one eye may be detected by having the patient follow the examiner’s finger or a bright flash through the cardinal movements of gaze. The eyes may move in a disconjugate fashion, or the patient may admit to diplopia if asked. Diplopia on extreme gaze in one direction may indicate entrapment of one of the extraocular muscles within a fracture site, but more often is caused simply by edema or hemorrhage related to the injury and is functional rather than actual entrapment. In the absence of trauma, diplopia is rarely associated with redness or pain.

**Pupillary Evaluation**

The pupils are inspected for abnormalities of shape, size, and reactivity. These examinations are conducted with light specifically directed into the pupil and by means of the swinging flashlight test.

Previous surgery (e.g., iridotomy for cataract extraction) and synechiae from prior iritis or other inflammatory condition are the most common causes of irregularly shaped pupils. Asymmetrically sized pupils may represent normal or pathologic conditions. Physiologic anisocoria is a slight difference in pupil size that occurs in up to 10% of the population. Topical or systemic medications, drugs, and toxins may cause abnormal pupillary constriction or dilation.

Pathologic reasons for failure of one pupil to constrict with a direct light stimulus include globe injury, abnormalities of afferent or efferent nerves, and paralysis of the ciliaris or sphincter pupillae muscles in the iris. Potentially serious problems, which also cause pain and redness, include uveitis and acute angle-closure glaucoma.

The swinging flashlight test is used to determine whether a relative afferent pupillary defect (RAPD) exists. The patient fixes the gaze on a distant object and the examination room is darkened. The size of the pupils in lowered light is noted, and unless there is physiologic anisocoria, the pupils should be equal in size. The direct and consensual light responses of the eyes are compared as a light source, angled into the pupil from in front of the cheeks, is swung back and forth between the two. When the light source shines into an eye with an RAPD, the pupil dilates because the consensual response from withdrawal of light from the opposite eye with normal afferent activity is stronger than the direct constrictive response to light in the affected eye with inhibited afferent activity. It is termed “relative” because the response is compared with that of the opposite side as the light source is alternated between eyes. An RAPD may be partial or complete and due to inhibition of light transmission to the retina because of vitreous hemorrhage, loss of some or all of the retinal surface for light contact because of ischemia or detachment, or the presence of lesions affecting the prechiasmal optic nerve (e.g., optic neuritis).

**Pressure Determination**

Ocular tonometry is usually the last examination performed in the emergency department. Common methods of determining the IOP in the emergency department include use of electronic, manual (e.g., Schiotz), or applanation tonometers. IOPs in the 10- to 20-mm Hg range are considered normal. Causes of intraocular hypertension include glaucoma in its many forms, suprachoroidal hemorrhage, and space-occupying retrobulbar pathology. Patients presenting with IOPs exceeding 20 mm Hg should have ophthalmologic consultation. Rapid treatment is usually not necessary until the pressure exceeds 30 mm Hg.

**Slit-Lamp Examination**

The slit lamp permits a magnified, binocular view of the conjunctivae and anterior globe for diagnostic purposes and to facilitate delicate procedures. It allows depth perception in otherwise clear structures, such as the cornea, aqueous humor, and lens. The slit-lamp examination can include the following:

- Lids and lashes may be inspected for blepharitis and point ing of a lid abscess (i.e., hordeolum). The inner canthus and lacrimal punctum may be better viewed for evidence of dacryocystitis.
- Punctures, lacerations, and inflammatory patterns of the conjunctiva or sclera may be discovered with magnification.
- Corneal abrasions, ulcers, foreign bodies, and other abnormalities may be seen. The depth of these lesions may be accurately assessed with an angled beam. Edema, which appears as a white haze or cloudiness within clear structures, can be differentiated within the epithelium or deeper stroma.
- The anterior chamber may be examined for cells (e.g., red and white blood cells) and “flare.” Cells are seen as small floating objects caught in the beam of a highly angulated slit-lamp light, as dust floating in the movie theater glows from the reflected light of the projector beam. Flare is a diffuse haziness, related to cells and proteins suspended in the aqueous humor, and is often visible only when illuminated directly (Fig. 32-3). It usually represents deep...

![Figure 32-3](image_url)
inflammation of the eye and is often seen in iritis. Collections of layered blood or pus in the dependent portions of the anterior chamber are called hyphema or hypopyon, respectively, and are graded by the percentage of the vertical diameter of the visible iris when the head is upright. Foreign bodies that have penetrated the cornea may be found floating in the anterior chamber.

- The trabeculated pattern of the iris can be seen in detail. Spiraling muscle fibers may be seen in acute angle-closure glaucoma. If the beam is shown almost coaxially with the examiner’s line of sight such that the red reflex is elicited, tears in the iris may be seen by light returning through the iris itself instead of just through the pupil.

- The lens should be examined for position, general clarity, and the presence of opacities or foreign bodies. The type and position of any lens implants can also be better assessed during a slit-lamp examination.

**Direct Funduscopic Examination**

Emergency physicians most commonly perform a nondilated funduscopic examination because there are several eye conditions in which dilation may be harmful (e.g., glaucoma). Iridodialysis, lens dislocation, and conditions requiring early intervention are usually identifiable along the visual axis.

- Inability to obtain a red reflex or visualize the fundus of the eye can be due to:
  - Opacification of the cornea, most commonly by edema secondary to injury or infection
  - Hyphema or hypopyon within the anterior chamber
  - Extremely miotic pupil
  - Cataract of the lens
  - Blood in the vitreous or posterior eye wall
  - Retinal detachment

In the absence of trauma, few posterior findings are associated with chief complaints of external redness. Findings associated with visual loss include pallor of the retina indicating ischemia, “cupping” of the optic disk indicating glaucoma, indistinctness of disk margins indicating papilledema or optic neuritis or neuropathy, air or plaque emboli in retinal arteries, and a host of other signs indicating more chronic ocular or systemic pathology not normally amenable to management in the emergency department.

**Bedside Testing**

Fluorescein solution and the cobalt blue lamp are the best means for identifying damage to the corneal epithelium, including that which cannot be seen with conventional slit-lamp examination. Fluorescein highlights defects, making them easy to identify, because the fluorescing liquid is thicker in defects than it is across the normally smooth corneal surface. Use of fluorescein may reveal corneal abrasions and ulcers as well as damage from keratitides related to chemicals, ultraviolet light, or infections (e.g., herpes).

Relief of discomfort after instillation of a topical anesthetic can be used as a diagnostic test for an external source of pain. In general, abolition of pain by local anesthetic drops indicates pain of corneal origin. Modest but incomplete relief suggests a conjunctival process. Intraocular pain is not diminished by local anesthetic solution. When ocular penetration is suggested, Seidel’s test can be used. This test involves placing a fluorescein strip directly over an area of possible corneal disruption. The high localized concentration of fluorescein may facilitate identification of the corneal defect with a slit lamp by allowing visualization of leaking aqueous fluid diluting the fluorescein. This test does not work on the conjunctiva overlying the sclera, and a negative test result does not rule out a full-thickness corneal injury.

**Ancillary Testing**

An erythrocyte sedimentation rate may be used to evaluate for temporal arteritis, which may arise with eye pain and decreased visual acuity.

Infections are usually evident by examination, and laboratory tests such as a complete blood count are not necessary. Microbiologic cultures are rarely ordered in the emergency department.

Plain radiography is used to identify facial fractures associated with facial or ocular trauma or indirectly by detecting an air-fluid level in the orbit or fluid in the paranasal sinuses. Computed tomography (CT), using 1.5-mm axial and coronal cuts, provides superior imaging, but is not necessary in many cases.

CT also reliably localizes metal and many nonradiopaque foreign bodies in the globe and orbit. It can also detect small amounts of intraocular air following penetrating trauma. Magnetic resonance imaging (MRI) clearly delineates the orbital and retro-orbital structures, but cannot be employed with metallic (magnetic) foreign bodies, which can migrate to cause additional damage. It is less often used in emergency eye assessment, for which, in general, CT is the initial imaging modality of choice. Ultrasonography is more sensitive for detecting intraocular foreign bodies, but CT is better at delineating the damage caused by them, so they are complementary tests.

**DIFFERENTIAL DIAGNOSIS**

Clinical findings most indicative of serious eye disorder are listed in Box 32-1.

**Critical Diagnoses**

Caustic injury to the eye can rapidly lead to a destructive keratoconjunctivitis (Fig. 32-4A and B) if the agent is not removed immediately. The diagnosis is made on history alone, before any other examination is performed. Early and copious irrigation is indicated. Many patients have already undergone extensive irrigation at the job site, but when the exposure has occurred in the home, irrigation prior to arrival in the emergency department is uncommon. Alkaline caustic agents cause a liquefactive necrosis of the cornea by progressively reacting with the corneal layers, and destruction is severe and relentless. Continuous irrigation is the only effective method to terminate the reaction and should be continued for at least 30 minutes. Acid injury is much less severe and requires less irrigation than alkaline exposures, but irrigation should continue until the pH of the tears is neutral or the patient is essentially asymptomatic.

Acute angle-closure glaucoma is a relatively rare but important critical diagnosis to make in the emergency department. Patients present with pain, the onset of which is often sudden in low-light conditions requiring pupillary dilation through contraction and thickening of the iris peripherally. The iris becomes immobile and often irregular, and the pupil is commonly fixed at 5 to 6 mm in diameter. Inability of the pupil to constrict may result in photophobia, and accommodation may be affected. These reactions and the increased IOP can lead to frontal headache, nausea, and vomiting. As inflammation progresses, limbal injection of the conjunctiva is almost universally seen. Figure 32-5 demonstrates many of these findings. Immediate medical intervention in the emergency department is indicated.
Corneal origin of the process and facilitating examination and definitive diagnosis. Corneal abrasions are very common and may be identified by white light or fluorescein-facilitated blue light using a slit lamp or any other magnification (Fig. 32-6). Following thorough irrigation, thermal and chemical burns must receive a careful slit-lamp examination for potential full-thickness injury. If this is not found, the corneal injury may be treated similarly to an abrasion.

In immunocompetent hosts, corneal ulcerations are most commonly due to overuse of contact lenses. They are seen as a denuding of epithelium with surrounding edema, the increased interstitial water of which is seen as whitish clouding of the normally clear tissue (Fig. 32-7). Almost all ulcerations require same-day evaluation by an ophthalmologist. Infections of the cornea with herpes simplex virus can rapidly lead to opacification and significant visual loss. It is most commonly recognized by a characteristic dendritic pattern of fluorescein pooling under blue light (Fig. 32-8). Anterior uveitis, which includes iritis and iridocyclitis, often occurs secondary to a traumatic injury or infectious process or can be associated with serious systemic immune diseases, such as adult and juvenile rheumatoid arthritis, sarcoidosis, and ankylosing spondylitis.

Scleritis is rare and may be difficult to differentiate from episcleritis, which is somewhat more common and a more
translucent, sclera (Fig. 32-9). Scleritis may be associated with anterior uveitis, cataract, and secondary glaucoma.

Endophthalmitis usually results from an infection of structures inside the globe. It is most common following penetrating trauma but may begin after hematogenous seeding from a remote or systemic infection, particularly in immunocompromised hosts. Unless it is detected early, and is responsive to aggressive antimicrobial therapy, endophthalmitis is a devastating process that frequently requires enucleation.

Urgent Diagnoses

Penetrating ocular trauma is evaluated by history (e.g., working with high-speed grinding equipment), examination (extrusion of aqueous humor or other globe content; direct visualization of a foreign body in the anterior chamber, vitreous, or retina), or identification of the offending object by biplanar plain radiography, thin-cut CT, or ultrasonography. MRI should not be used if there is any possibility that the foreign object may be metallic. Indirect indicators of globe penetration are hyphema, an irregularly shaped pupil from traction on or injury to the iris' attachments, or lack of a red reflex. If penetrating ocular injury is confirmed or if the possibility persists after evaluation, an ophthalmologic consultation is indicated.

Spontaneous or traumatic hyphema is often managed conservatively. Blood in the anterior chamber is usually the result of direct ocular trauma and may be associated with traumatic mydriasis or an obvious tear of the iris. If penetration and rupture can be reasonably excluded, the hyphema should be graded and IOP determined. Intraocular hypertension (or hypotension in the case of occult globe rupture) following trauma must also be evaluated by an ophthalmologist urgently. Inability to view posterior structures through the anterior blood may necessitate radiologic or ultrasonographic imaging.

Diagnostic Algorithm

A recommended algorithmic approach to the patient with an acute red eye is provided in Figure 32-10.

**Figure 32-10.** Diagnostic algorithm for red eyes. *Indicates potentially serious diagnoses if not identified on initial emergency department evaluation. †Purulent implies true pus, as opposed to the mucoid discharge more commonly associated with nonbacterial causes of conjunctivitis. a.k.a., also known as; FB, foreign body; incl, including. (Modified from Trobe JB: The Physician’s Guide to Eye Care. San Francisco, Foundation of the American Academy of Ophthalmology, 2001.)

---

**EMPIRICAL MANAGEMENT**

**Irrigation**

Any clean water is appropriate for irrigation, and prompt initiation takes precedence over procurement of a particular irrigating solution. The most important principles are rapid and copious dilution and removal of the offending material. An eyewash station or faucet with tap water may be employed. Normal saline may be instilled through the end of macrodrip intravenous administration tubing. If there is no gross eye injury, a Morgan lens may be attached to this tubing, but emergency department staff do not have to help the patient hold the eye open. Quickly administering two drops of topical anesthetic and allowing 30 seconds or so for the anesthetic to become effective greatly facilitates patients’ tolerance of the prolonged irrigation required. It is recommended that the first 500 to 1000 mL of irrigation fluid be...
administered while examining the eye; then the Morgan lens may be placed.

**Pain Relief**

Pain often interferes with obtaining an adequate assessment. A topical anesthetic, such as proparacaine 0.5%, may facilitate cooperation in patients with possible injury or inflammation of the anterior eye by reducing pain and blepharospasm long enough to obtain a targeted history and focused examination. Topical anesthetic agents should not be given to patients to use at home. Parenteral or oral analgesics can be used for severe deep pain not amenable to topical relief in the emergency department, or for outpatient management of discomfort after discharge.

**Mydriatic and Cycloplegic Agents**

Dilation of the pupil is not usually necessary in the emergency department for funduscopic examination, but may relieve pain associated with ciliary spasm in anterior uveitis. Mydriatic agents (e.g., phenylephrine, tropicamide) merely prevent constriction of the pupil by paralyzing the sphincter pupillae muscle of the iris. Cycloplegic agents (e.g., cyclopentolate, homatropine) paralyze the ciliaris muscle, with an accompanying mydriatic effect. The agent chosen should be guided by the desired length of time of mydriasis for the particular condition being treated (Table 32-1). Mydriatic agents are contraindicated in patients with narrow-angle glaucoma.

**Antimicrobial Agents**

Most conjunctivitis is viral in origin, but it is often difficult to distinguish bacterial from viral types of conjunctivitis based solely on clinical grounds. Although no definitive empirical evidence dictates the use of antibiotic solutions or ointments for surface infections, the use of broad-spectrum topical antibiotics in cases of proven bacterial conjunctivitis is associated with benefit showing significantly higher clinical remission rates. Antimicrobial prophylaxis should be used for penetrating wounds to prevent bacterial keratitis or conjunctivitis associated with ciliary spasm in anterior uveitis. Mydriatic agents (e.g., phenylephrine, tropicamide) merely prevent constriction of the pupil by paralyzing the sphincter pupillae muscle of the iris. Cycloplegic agents (e.g., cyclopentolate, homatropine) paralyze the ciliaris muscle, with an accompanying mydriatic effect. The agent chosen should be guided by the desired length of time of mydriasis for the particular condition being treated (Table 32-1). Mydriatic agents are contraindicated in patients with narrow-angle glaucoma.

*Mydriatic action only, no cycloplegic effect. Combination products such as Cyclomedril, which is cyclopentolate 0.2% and phenylephrine 10%, are also available.

**Other Protective Interventions**

Significantly increased IOP must be reversed as rapidly as possible, often before the specific cause is known. After placing the patient in at least a 30° head-up position, two drops of timolol 0.5%, a topical beta-adrenergic blocking medication, should be administered as a first-line agent to decrease the production of aqueous humor. This may be followed by two drops of dorzolamide 2%, a topical carbonic anhydrase inhibitor, to reduce aqueous humor production further. If not available, 500 mg of acetazolamide may be given orally or intravenously. If the patient has sickle cell disease or trait, oral methazolamide 50 mg must be used instead. Patients with suggested intraocular hypertension who also have nausea or vomiting should receive a parenteral antiemetic so that they do not gag or vomit, which may further increase IOP.

**Specific Management**

Management of the specific entities listed in the diagnostic algorithm presented in Figure 32-10 is presented in Table 32-2. Specific management of ophthalmologic conditions is also discussed in Chapter 69.

**SPECIAL CONSIDERATIONS**

**Pediatrics**

A red eye in a neonate or infant is always abnormal. It is usually caused by corneal abrasion or infection. Corneal abrasions can also be a cause of inconsolable crying in an infant. Fluorescein examination helps to identify abrasions and herpes keratitis, acquired from the birth canal. *Chlamydia* infections may also be acquired during vaginal deliveries but may not arise for weeks. These infections should be treated with oral azithromycin as well as parenteral ceftaxime to cover *Neisseria gonorrhoeae*. Conjunctivitis associated with respiratory symptoms or infiltrates on a chest radiograph in an infant younger than 3 months should be treated with an oral macrolide. Oral antibiotics are also indicated for conjunctivitis associated with otitis media. *Mycoplasma* is a common infectious agent in these cases, and a macrolide is indicated.

<td>Outpatient referral only for treatment failure after 2 wk.</td>
</tr>
<tr>
<td>3. Chalazion</td>
<td>Inflammation of meibomian gland causing subcutaneous nodule within the eyelid.</td>
<td>None.</td>
<td>Outpatient referral only for treatment failure after 2 wk.</td>
</tr>
<tr>
<td>4. Dacrocystitis and dacroadenitis</td>
<td>Eye tearing and inflammation of lower eyelid inferior to lacrimal punctum finding redness and tenderness over nasal aspect of lower lid and adjacent periorbital skin.</td>
<td>First t/o periorbital cellulitis (#9) and orbital cellulitis (#7). Inspect for obstruction of punctum by SLE, may express pus by pressing on sac, PO Rx for nasal and skin flora if not admitting.</td>
<td>Ophthalmologist may admit if systemically ill, case is moderate or severe, or no social support for patient. Ask about culturing before Rx if admitting, then Rx same as for periorbital cellulitis (#9).</td>
</tr>
<tr>
<td>5. Hordeolum (a.k.a. stye)</td>
<td>Abscess in eyelash follicle or modified sebaceous gland at lid margin: external or internal based on side of lid margin that abscess is pointing.</td>
<td>Measure IOP. Evaluate for infection, diabetes mellitus, and vasculitis with CBC, BMP, UA, and ESR. Obtain axial CT of brain and axial and coronal CT of orbits and sinuses.</td>
<td>May discharge mild cases with PO analgesics and antibiotics (e.g., amoxicillin/clavulanate), and instructions to apply warm compresses to eyelids for 15 min and gently massage nodule qid.</td>
</tr>
<tr>
<td>6. Inflammatory pseudomembranous</td>
<td>Non-specific idiopathic retrobulbar inflammation with eyelid swelling, palpebral injection of conjunctiva, chemosis, proptosis, blurred vision, painful or limited ocular mobility, binocular diplopia, edema of optic disk, or venous engorgement of retina.</td>
<td>IOP &gt; 20 mm Hg may be surgical emergency, Rx to decrease IOP in ED.</td>
<td>May discharge if no systemic problems, no findings of particular concern on CT, and IOP &gt; 20 mm Hg. Start high-dose PO steroids after discussion with ophthalmologist and ensure reevaluation in 2–3 days.</td>
</tr>
<tr>
<td>7. Orbital cellulitis</td>
<td>Eyelid swelling, redness and warmth of skin overlying orbit, tenderness of skin overlying bone palpebral injection of conjunctiva, chemosis. Differentiated from periorbital cellulitis by presence of any finding of fever, ill appearance, blurred vision, proptosis, painful or limited ocular mobility, binocular diplopia, edema of optic disk, or venous engorgement of retina.</td>
<td>Measure IOP. Start IV Rx with second-generation cephalexin (e.g., cefuroxime, cefotaxin, or cefotetan) or with ampicillin/sulbac tam to cover skin and skin flora. Alternative Rx is ticarcillin/clavulanate, piperacillin/azobactam, vancomycin, or clindamycin + third-generation cephalexin (e.g., cefotaxime or ceftriaxone).</td>
<td>Admit all cases of orbital cellulitis.</td>
</tr>
<tr>
<td>8. Orbital tumor</td>
<td>Blurred vision, proptosis or other displacement of globe, painful or limited ocular mobility, or binocular diplopia (but can be asymptomatic).</td>
<td>Measure IOP. Evaluate for extracocular signs of malignancy. Obtain axial CT of brain and axial and coronal CT of orbits and sinuses.</td>
<td>Based on findings and discussion with consultant.</td>
</tr>

<tr>
<td>9. Periorbital cellulitis or erysipelas Eyelid swelling, redness and warmth of skin overlying orbit, tenderness of skin overlying bone, palpebral injection of conjunctiva, and chemosis. Differentiated from orbital cellulitis by absence of any other finding listed in #7.</td>
<td>First t/o orbital cellulitis (#7). PO Rx for sinus and skin flora if not admitting.</td>
<td>Ophthalmologist may admit if systemically ill, case is moderate or severe, or no social support for patient.</td>
<td>May discharge mild cases with PO antibiotics. Ophthalmologist must reevaluate next day to ensure no orbital extension.</td>
</tr>
<tr>
<td>10. Retrobulbar abscess* Findings of orbital cellulitis (#7) but a/w increased IOP.</td>
<td>Measure IOP unless possibility of ruptured globe. IOP &gt; 30 mm Hg may require emergent needle aspiration or lateral canthotomy and cantholysis in ED.</td>
<td>IOP &gt; 20 mm Hg may be surgical emergency. Rx to decrease IOP in ED. Obtain axial CT of brain and axial and coronal CT of orbits and sinuses.</td>
<td>Admit all cases of retrobulbar pathology causing increased IOP. Others might be candidates for discharge depending on cause of problem.</td>
</tr>
<tr>
<td>12. Retrobulbar hematoma* Findings of pseudotumor (#6) but occurs due to trauma, coagulopathy, or thrombocytopenia and a/w diffuse subconjunctival hemorrhage anteriorly and extending posteriorly as well as increased IOP.</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>13. Keratitis (abration or UV injury) Pain, FB sensation, blepharospasm, tearing, photophobia, epithelial disruption on inspection under white light or fluorescein pooling under blue light. SPK appears as stippling of corneal surface [often lower 2/3 of cornea if due to light exposure]. Keratitis (ulceration)* Symptoms and signs as above. Ulceration from complications of contact wear or neglected corneal abrasion has “scopped out” epithelium with surrounding edema appearing as white “cloudiness” in clear tissue. Keratitis (herpetic infection)* Symptoms and signs as above. Look for other signs of herpes, varicella, zoster (or CMV infection in immunocompromised patient). Look for “dendritic” defects of cornea with fluorescein under blue light.</td>
<td>First t/o corneal penetration either grossly or employing Seidel’s test. Relieve pain and blepharospasm with topical anesthetic. Inspect all conjunctival recesses and superficial cornea for any foreign material that can be removed by irrigation or manually lifted from surface. Tetanus prophylaxis is standard of care even if cornea not penetrated.</td>
<td>Ophthalmologist must come to ED if there is any concern for globe penetration. Otherwise consult for follow-up examination in 1–2 days. One-time administration of cycloplegic agent may limit photophobia until follow-up examination. Discuss any potential need to débride or culture before starting antibiotic. Based on findings and discussion with consultant. Typical ciprofloxacin dosing is 1 gt. q 15 min for 1 hr, then 1 gt. q hr for 8 hr, then 1 gt. q 4 hr until seen by consultant next day. PO NSAIDs or narcotics for analgesia. Patching not necessary.</td>
<td>May discharge cases not infected or ulcerated on topical antibiotic prophylaxis using polymyxin B combinations with bacitracin (ointment) or trimethoprim (solution). Gentamicin and sulfacetamide are less desirable single-agent alternatives. PO NSAIDs or narcotics for analgesia. Patching not necessary.</td>
</tr>
</tbody>
</table>
### 14. Keratoconjunctivitis
Conjunctivitis with subepithelial infiltrates in cornea causing pain and decreased vision, possibly with halos reported.

- **Diagnosis**
  - From Figure 32-10

- **Management Consultation**
  - Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist).

- **Disposition**
  - May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2–3 days.

### 15. Episcleritis
Rapid onset of localized pain, injection of episcleral vessels, and localized tenderness.

- **Diagnosis**
  - Conjunctivitis with subepithelial infiltrates in cornea causing pain and decreased vision, possibly with halos reported.

- **Management Consultation**
  - Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist).

- **Disposition**
  - May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2–3 days.

### 16. Scleritis
Progressively increasing eye pain with radiation to ipsilateral face and decreasing vision, photophobia, tearing, and possible pain with eye motion.

- **Diagnosis**
  - Conjunctivitis with subepithelial infiltrates in cornea causing pain and decreased vision, possibly with halos reported.

- **Management Consultation**
  - Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist).

- **Disposition**
  - May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2–3 days.

### 17. Anterior uveitis and hypopyon
Eye pain, photophobia, tearing, limbal injection of conjunctiva, and cells or flare in anterior chamber. Hypopyon is layering of white cells (pus) in anterior chamber.

- **Diagnosis**
  - Conjunctivitis with subepithelial infiltrates in cornea causing pain and decreased vision, possibly with halos reported.

- **Management Consultation**
  - Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist).

- **Disposition**
  - May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2–3 days.

### 18. Acute angle-closure glaucoma
Sudden-onset eye pain and blurred vision that may be with frontal headache, nausea, and vomiting. Anterior eye may manifest shallow or closed angle between iris and cornea, pupil fixed in mid-dilation, or limbal injection of conjunctiva.

- **Diagnosis**
  - Conjunctivitis with subepithelial infiltrates in cornea causing pain and decreased vision, possibly with halos reported.

- **Management Consultation**
  - Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist).

- **Disposition**
  - May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2–3 days.

### 19. Hyphema
Pain, decreased visual acuity, gross or microscopic blood in anterior chamber, may be with dilated and fixed pupil following blunt trauma.

- **Diagnosis**
  - Conjunctivitis with subepithelial infiltrates in cornea causing pain and decreased vision, possibly with halos reported.

- **Management Consultation**
  - Discuss findings and use of prednisolone acetate 1% (frequency determined by ophthalmologist).

- **Disposition**
  - May discharge patient with medications recommended by ophthalmologist and ensure reevaluation in 2–3 days.

*Potentially serious diagnoses if not identified on initial emergency department evaluation. Antibiotic choices should be based on current practice.

a.k.a., also known as; a/w, associated with; bid, twice daily; BMP, basic metabolic profile (includes electrolytes, glucose, and renal function tests); CBC, complete blood count; CMV, cytomegalovirus; CT, computed tomography; ED, emergency department; ESR, erythrocyte sedimentation rate; FB, foreign body; gtt, drop; gtt, drops; IOP, intraocular pressure; LP, lumbar puncture; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs; PO, oral; q, every; qid, 4 times a day; r/o, rule out; Rx, prescribe; SLE, slit-lamp examination; SPK, superficial punctuate keratitis; spp, species; Staph., *Staphylococcus*; Strep., *Streptococcus*; UA, urinalysis; US, ultrasonography; UV, ultraviolet.
Trauma

Blunt trauma is a common cause of a red and painful eye. Large hyphemas and those with clots are likely to require hospitalization for bedrest with 30° of head elevation. Systemic analgesia and, if required, antiemetics are indicated. Medications affecting platelet function should be avoided. Treatment may be indicated when the IOP exceeds 30 mm Hg, as it is in acute angle-closure glaucoma. If the iris is not injured, a long-acting cycloplegic agent (e.g., topical homatropine) may be recommended to prevent repetitive motion of the iris. Some reliable adult patients may be discharged with daily follow-up by a specialist. Strong analgesia and patching are not indicated, so that the patient may immediately identify increases in pain or decreases in visual acuity.

Corneal abrasions are common problems in the emergency department. When the emergency physician is convinced that the cornea has not received a full-thickness laceration or penetration by a foreign body, management is relatively simple. Foreign bodies (on or in the epithelium only) should be removed when possible. These may frequently adhere to a saline-moistened cotton-tipped applicator. Ones that do not may sometimes be lifted off with a blunt-tipped tool (“spud”) under the binocular magnification of a slit lamp. The common use of hypodermic needle removal may damage surrounding cornea and is not recommended. Whether or not the object can be successfully removed, management is the same as for corneal abrasions. Rust staining of the corneal epithelium does not require removal in the emergency department, but patients are referred to a specialist for examination within 3 days. Prophylactic topical antibiotics are indicated for all epithelial defects of the cornea. Patching is not necessary and may be harmful. Systemic analgesia appropriate to the patient’s level of pain should be provided. Larger lesions may require a prophylactic mydriatic or cycloplegic agent anticipating a secondary iritis. Topical anesthetics should not be given to the patient for home use.

**DISPOSITION**

Most emergency department patients with eye complaints are candidates for discharge and, if indicated, follow-up in the emergency department or with an ophthalmologist in 1 to 2 days. Others may require referral only if there is lack of resolution or treatment fails. A few patients require admission for procedural intervention, parenteral antibiotic regimens, management of intractable pain, or further diagnostic evaluation. General consultation and disposition considerations for the most important entities are outlined in Table 32-2.

Trauma
The care of the injured patient remains one of the mainstays of emergency medicine practice. Emergency physicians play a vital role in the stabilization and diagnostic phases of trauma care. Management of these patients involves complex, time-dependent decision-making, leadership capability, and technical skill. Proper resuscitation can lead to functional outcomes, even in severely injured patients.1

### EPIDEMIOLOGY

In 2004, there were 167,184 injury-related deaths, of which 73% were motor vehicle–related, firearms-related, or caused by poisonings or falls. Unintentional accidents were the leading cause of death in people ages 1 to 44 years. Motor vehicle collisions (MVCs) made up the largest percentage of those accidents, accounting for 26% of all injury-related deaths.2 The number of motor vehicle deaths has remained relatively stable for the past decade. The number of people injured in motor vehicle crashes, however, has declined 22% during the same time period, to 2.7 million in 2005.3 Homicide is one of the top five leading causes of death in people ages 1 to 44 years, with firearm injuries accounting for 17.7% of all injury deaths in 2004.2

The economic cost of traumatic injuries is staggering. It is estimated that the total cost of injuries that occurred in 2000 is $406 billion; this includes medical costs and lost productivity. Motor vehicle and fall injuries account for 22% ($89 billion) and 20% ($81 billion) of this total, respectively.3

Many of these injuries are avoidable. Proper use of lap/shoulder belts can reduce the risk of fatal injury by 45%.2 Yet, in 2005, it is estimated that 55% of MVC occupant fatalities were unrestrained; this percentage increases to 65% for the 21- to 24-year-old age group.4 Child safety seats reduce the risk of death in passenger cars by 71% for infants and by 54% for toddlers ages 1 to 4 years.5 Educational and law enforcement initiatives addressing seat belts, proper child restraint, drinking and driving, gun safety, and fall prevention can assist in raising public awareness. The National Highway Traffic Safety Administration’s (NHTSA) “Click-it or Ticket” campaign increased belt use in 41 of 50 states and the District of Columbia during a 2-month time period.3 NHTSA has a similar program aimed at drunk driving called “Over the limit. Under arrest.” The effect of firearm laws on decreasing firearm violence is less concrete (even though a decrease has been seen).8 Further study is needed to determine the impact of legislation, public education, and prevention programs on firearm violence.

### TRAUMA SYSTEMS

The first document to set criteria for categorizing hospitals as trauma centers was promulgated by the American College of Surgeons (ACS) Committee on Trauma in 1976.9 As other groups recognized the importance of structured trauma care, legislation and funding to promote the development of trauma systems grew. In the early 1990s, the Health Resources and Services Administration developed the Model Trauma Care System Plan, a well-designed framework for progress measurement in trauma systems. Unfortunately, this program lost funding in 2006. As of 1998, 38 states and the District of Columbia had at least one critical element in place for a formal trauma system.10 More up-to-date data are not readily available because the program was the main source for this information.

The benefit of regionalized trauma systems has been shown in multiple studies. A meta-analysis of 14 studies demonstrated an overall 15% decline in mortality due to the presence of a trauma system.11 However, this apparent decline may be confounded by other factors. A nationwide study suggests that mortality reduction could not be solely attributed to the presence of a trauma system because its impact was small and statistically not significant. Rather, the presence of a primary seat belt law and mean per capita income were associated with a reduction in occupant mortality rates, whereas rural population and speed limits faster than 65 mph were associated with an increase in mortality rates.12 As new trauma systems mature, more research will be needed to guide implementation of new system strategies to further reduce morbidity and mortality from traumatic injury.

One goal of the out-of-hospital trauma system is to transport the patient to the closest appropriate facility in a timely manner. Problems with over- and undertriage occur. Most efforts are aimed at reducing undertriage (transport of severely injured patients to lower level trauma centers), which may result in preventable morbidity and mortality from delay in definitive care. Overtriage (transport of minimally injured patients to higher level trauma centers) has no deleterious effects on patient care; however, it may contribute to unneces-
susceptibility to sheer forces and other aspects of trauma. These changes can increase organ system function related to decreased cardiopulmonary trauma patients typically have normal, age-related changes in majority of these occur as the result of a fall or an MCV. Elder sustain extremity, craniofacial, and closed head injuries. The emergency physician should anticipate more widespread inju-

Injury patterns can differ significantly between adults and children subjected to similar mechanisms of trauma. The major anatomic distinctions relate to the smaller size and surface area, larger head-to-body ratio, and less protected abdominal cavity of the child. As a result, children are more vulnerable to multisystem injury in blunt trauma, more frequently sustain significant head and intra-abdominal injuries, and are more at risk for hypothermia.

Trauma is the seventh leading cause of death in patients older than the age of 65 years. Elder patients commonly sustain extremity, craniofacial, and closed head injuries. The majority of these occur as the result of a fall or an MCV. Elder trauma patients typically have normal, age-related changes in organ system function related to decreased cardiopulmonary functional reserve, decreased renal function, decreased bone density, and cerebral atrophy. These changes can increase susceptibility to shear forces and other aspects of trauma.

Comorbidities and preexisting medication use further complicate the management of elder trauma patients. Lower extremity weakness, gait disturbances, decreased visual acuity, and the use of psychotropics, antihypertensives, and sedatives have been associated with falls in elders, resulting in major injury. The use of these medications, particularly antihyper-
tensives, should not be considered causative in trauma patients with hypotension until acute hemorrhage is assessed and managed. In addition, anticoagulants, antiplatelet drugs, and aspirin are commonly prescribed, and their effects should be suspected and reversed if possible in elder trauma patients.

## MANAGEMENT

### Out-of-Hospital

Management of the trauma patient frequently begins prior to arrival in the emergency department by first responders. The goals of out-of-hospital care include intervening in immediately life-threatening injuries, preventing additional injury, and rapid transport to trauma centers for definitive care. Although accepted as tenets of out-of-hospital care, controversy exists regarding each of these goals.

The majority of life-threatening injuries that require intervention by out-of-hospital providers are related to airway, breathing, and circulation (the ABCs). Preventing aspiration of gastric contents and providing adequate tissue oxygenation are the primary goals of endotracheal intubation. Although controversy exists regarding the use of out-of-hospital rapid sequence induction, securing an unprotected airway is essential in this phase of trauma management. Tension pneumothorax is the fundamental threat to adequate ventilation and requires immediate needle thoracostomy. Systemic hypotension with impaired end-organ perfusion mandates treatment in the trauma patient, despite the debate surrounding controlled hypotension versus aggressive fluid resuscitation.

Preventing additional injury requires an awareness of not only clinically evident abnormalities but also potentially more serious injuries. Coordinated extrication and transport with rigid cervical immobilization, complete spinal precautions, intensive hemodynamic monitoring, and stabilization of fractures to prevent neurovascular compromise are examples of assuming the most serious injuries exist in multiple trauma patients.

In the United States, rapid transport to the nearest appropriate facility is one of the fundamental concepts in trauma management. Much of the controversy regarding various out-of-hospital approaches to the ABCs is rooted in attempts to limit transport times and avoid further infringement on the “golden hour” of trauma care. In contrast, physician-operated emergency medical service (EMS) systems more aggressively manage airway and ventilatory issues and are more likely to commit out-of-hospital time resources to establishing hemodynamic stability prior to transport. Rural EMS systems in the United States, where transport times may be prolonged because of the distance to a receiving facility, may benefit from more advanced interventions such as rapid sequence induction/intubation and more aggressive fluid resuscitative measures.

### Emergency Department

#### General Principles

Care of the multiple trauma patient is complex and involves the coordination of multiple providers, including EMS personnel, emergency physicians, nurses, technicians, trauma surgeons, and subspecialists. A systematic and comprehensive approach to these patients is necessary, incorporating providers from each discipline. Advanced Trauma Life Support (ATLS) guidelines delineate the use of defined trauma response teams, with providers performing assessments, diagnostics, and interventions simultaneously. With this approach,

the physician team leader coordinates the management of the patient, considering the presence of life- or limb-threatening injuries in a sequential manner.

For level 1 trauma centers, the ACS mandates the presence of a surgeon or an appropriate representative (e.g., a fourth- or fifth-year surgery resident) to be present in the hospital 24 hours a day. The attending surgeon is expected to be present in the emergency department no later than 15 minutes after the emergency department arrival of trauma patients (Table 33-2). As the specialty of emergency medicine has evolved and the number of residency-trained and board-certified emergency physicians has increased, the need for a surgeon for all trauma patients has been increasingly debated. Optimal emergency physician has increased, the need for a surgeon for all trauma patients has been increasingly debated.30-34 Maintenance of PaO₂ greater than 60 mm Hg has been recommended. Inadequate ventilation, which may lead to respiratory acidosis, can be noted by the rate and quality of respirations. Signs of inadequate oxygenation may be more subtle and include agitation and restlessness. Assessment for injury that may compromise oxygenation, ventilation, or both requires careful inspection and auscultation of the chest. Signs of such compromising injury include increased work of breathing, tachypnea, penetrating wounds, flail segments, tracheal deviation, and distended neck veins. In determining the need for more aggressive airway management, these data are put into the context of the patient’s overall presentation. Certain ventilatory problems, such as pneumothorax or hemothorax, may require tube thoracostomy in addition to intubation. Early intervention is preferable in the tenuous patient.

Once the decision to intubate the patient has been made, many considerations must be taken into account. If the patient’s condition allows, a brief neurologic examination prior to paralytics can be helpful in determining the extent of injury. Also, cervical spine injury precautions should be considered for patients with blunt trauma and gunshot wounds to the neck. Rapid sequence induction and orotracheal intubation with in-line cervical stabilization provides a safe method. There have been no reported cases of spinal cord injury from orotracheal intubation if proper stabilization has been applied. There are many approaches to airway control, and many alternative devices, such as the flexible fiberoptic scope, intubating laryngeal mask airway, and video-assisted laryngoscope, are now available to assist in intubation. The choice will be based on clinical scenario and physician comfort. A review of the literature did not reveal one superior modality for intubation of the patient with suspected spinal cord injury. Nasotracheal intubation is generally undesirable in trauma patients due to the potential for abrupt rises in intracranial pressure, a higher complication rate than that for orotracheal intubation, and relative contraindications of severe midface trauma or severe basilar skull fracture.

Surgical airways are indicated in cases of failure or contraindication to orotracheal or nasotracheal intubation. Cricothyrotomy is the preferred method. A variety of devices for percutaneous cricothyrotomy are available that show good success rates and are easy to use. If there is any question of the ability to identify the cricothyroid membrane, the traditional surgical approach with a vertical incision should be used.

Circulation. Assessment of hemodynamics and circulatory status are of critical importance after the airway has been evaluated and controlled and adequate ventilation has been ensured. The assessment of circulation is multidimensional. Clinical indicators of adequate perfusion include mental status, skin color and temperature, heart rate, blood pressure, and capillary refill. A normal finding of any single sign does not rule out shock. Mental status changes associated with hypoperfusion can include anxiety, agitation, or sedation. Cool, pale skin or extremities with delayed capillary refill suggest inadequate perfusion and shock. A normal heart rate and/or blood pressure can be present despite significant hemorrhage. Conversely, tachycardia may be seen without evidence of significant volume loss.

Control of external hemorrhage is crucial. Traditionally, direct pressure to external bleeding sites has been advocated and the use of tourniquets has been discouraged. The use of direct pressure on bleeding remains first-line therapy; recent

Primary Survey

Airway and Breathing. Proper assessment and management of airway, oxygenation, and ventilation in the trauma patient is of utmost importance but can be challenging. In a review of 44,404 trauma patient admissions and 2594 deaths, airway management was responsible for 16% of preventable errors likely contributing to trauma mortality. The goals of airway management are threefold: airway protection, adequate oxygenation, and adequate ventilation.

Airway protection is necessary in a variety of trauma patients. Airway obstruction mandates immediate intervention. Obstruction from debris, blood, or vomitus may be easily removed with suction. Neck or facial trauma may be more problematic. Swelling, distorted anatomy, and hematoma formation may all contribute to impending obstruction. Early airway control is safest because these conditions may rapidly worsen. Inability to adequately protect the airway, such as in patients with depressed levels of consciousness, is another indication for intervention. Airway control is recommended in patients with significant head injury (GCS ≤ 8).

As a general rule, all trauma patients should be placed on supplemental oxygen. Adequate oxygenation has a direct effect on outcome of many trauma patients. In head-injured patients, hypoxia in both out-of-hospital and hospital phases of resuscitation has been associated with poorer outcomes. Hypoxia may also worsen outcome in spinal cord injury. Maintenance of PaO₂ greater than 60 mm Hg has been recommended. Inadequate ventilation, which may lead to respiratory acidosis, can be noted by the rate and quality of respirations. Signs of inadequate oxygenation may be more subtle and include agitation and restlessness. Assessment for injury that may compromise oxygenation, ventilation, or both requires careful inspection and auscultation of the chest. Signs of such compromising injury include increased work of breathing, tachypnea, penetrating wounds, flail segments, tracheal deviation, and distended neck veins. In determining the need for more aggressive airway management, these data are put into the context of the patient’s overall presentation. Certain ventilatory problems, such as pneumothorax or hemothorax, may require tube thoracostomy in addition to intubation. Early intervention is preferable in the tenuous patient.

Once the decision to intubate the patient has been made, many considerations must be taken into account. If the patient’s condition allows, a brief neurologic examination prior to paralytics can be helpful in determining the extent of injury. Also, cervical spine injury precautions should be considered for patients with blunt trauma and gunshot wounds to the neck. Rapid sequence induction and orotracheal intubation with in-line cervical stabilization provides a safe method. There have been no reported cases of spinal cord injury from orotracheal intubation if proper stabilization has been applied. There are many approaches to airway control, and many alternative devices, such as the flexible fiberoptic scope, intubating laryngeal mask airway, and video-assisted laryngoscope, are now available to assist in intubation. The choice will be based on clinical scenario and physician comfort. A review of the literature did not reveal one superior modality for intubation of the patient with suspected spinal cord injury. Nasotracheal intubation is generally undesirable in trauma patients due to the potential for abrupt rises in intracranial pressure, a higher complication rate than that for orotracheal intubation, and relative contraindications of severe midface trauma or severe basilar skull fracture.

Surgical airways are indicated in cases of failure or contraindication to orotracheal or nasotracheal intubation. Cricothyrotomy is the preferred method. A variety of devices for percutaneous cricothyrotomy are available that show good success rates and are easy to use. If there is any question of the ability to identify the cricothyroid membrane, the traditional surgical approach with a vertical incision should be used.

Circulation. Assessment of hemodynamics and circulatory status are of critical importance after the airway has been evaluated and controlled and adequate ventilation has been ensured. The assessment of circulation is multidimensional. Clinical indicators of adequate perfusion include mental status, skin color and temperature, heart rate, blood pressure, and capillary refill. A normal finding of any single sign does not rule out shock. Mental status changes associated with hypoperfusion can include anxiety, agitation, or sedation. Cool, pale skin or extremities with delayed capillary refill suggest inadequate perfusion and shock. A normal heart rate and/or blood pressure can be present despite significant hemorrhage. Conversely, tachycardia may be seen without evidence of significant volume loss.

Control of external hemorrhage is crucial. Traditionally, direct pressure to external bleeding sites has been advocated and the use of tourniquets has been discouraged. The use of direct pressure on bleeding remains first-line therapy; recent
data have suggested the more liberal use of tourniquets for massive extremity bleeding that is not easily controlled.\textsuperscript{50-53} Similarly, recent studies of newer hemostatic agents have shown potential application both in combat and out-of-hospital settings.\textsuperscript{54-57}

Intravenous access is required early in the assessment of circulation. Two large-bore (14- or 16-gauge) intravenous catheters are recommended. Routine intravenous access may be difficult or unobtainable in certain cases. Intravenous vascular access can be obtained rapidly in both pediatric\textsuperscript{58} and adult\textsuperscript{59} patients and allows the safe infusion of large amounts of fluid or blood products. Compact, battery-operated intravenous drills have recently been introduced. Ultrasound-guided peripheral venous access should be considered in patients when blind peripheral attempts are unsuccessful.\textsuperscript{60-62} Central venous access may also be indicated in the appropriate clinical scenario or based on physician discretion. The use of ultrasound has been shown to increase successful vein cannulation and decrease complications in the placement of central venous lines.\textsuperscript{63-67} Central venous pressure measurements may be used to direct resuscitative efforts but should not delay definitive care.

The choice of fluids for resuscitation includes crystalloid, colloid, and blood products. Fluid replacement is generally based on a 3:1 ratio of fluids to blood loss. There are few clinically significant differences between lactated Ringer’s and normal saline. The debate regarding the choice of fluid for resuscitation is ongoing. No indisputable advantages of colloids have been demonstrated. Therefore, the less expensive and more readily available crystalloids are the routine mainstay as first line of therapy. No clear benefit to the use of hypertonic saline has been established.\textsuperscript{68-71} Current ATLS guidelines standardize the ratio of replacement fluids to loss and recommend 2 L of crystalloid be infused in all patients in shock, followed by blood products. O-positive blood should be used except in women of childbearing age. Type-specific blood should be used when available, but emergent transfusion should not be delayed.

The concept of “permissive hypotension” is based on the concern that resuscitation to normal blood pressures may increase bleeding from a site that is contained and not actively hemorrhaging.\textsuperscript{72} Clinically, restoration of normal blood pressure is delayed until active bleeding foci are ruled out. Although data exist to support this strategy,\textsuperscript{72,73} a Cochrane review of the six available clinical trials meeting inclusion criteria did not support (or disprove) the use of early or larger volume intravenous fluids in uncontrolled bleeding.\textsuperscript{74} Permissive hypotension is contraindicated in the management of traumatic brain injury because of the risk of hypoperfusion.\textsuperscript{75,76}

The extended focused abdominal sonography in trauma (eFAST) examination should be performed on all patients as an adjunct to the assessment of circulation. The presence or absence of free intra-abdominal, -thoracic, or -pelvic hemorrhage or pneumothorax diagnosed by ultrasound will direct the management of trauma patients. Pericardial effusions or tamponade can be readily identified. In addition, ultrasound evaluation of the inferior vena cava may be useful in the overall assessment of fluid status in resuscitation.\textsuperscript{77-81}

\textbf{Disability.} A rapid assessment of the patient’s neurologic status is necessary early in the emergency department course. The Glasgow Coma Scale score is commonly employed (see Chapter 38).

\textbf{Exposure.} The final phase of the primary survey is completely undressing the patient in order to assess for inconspicuous injuries. Special attention to the axilla, perineum, and skin folds is needed. Preventing hypothermia is essential in this phase. Blankets, warming lights, and warm fluids may be used as indicated.

\textbf{Secondary Survey}

The goals of the secondary survey are to obtain pertinent historical data about the patient and injury as well as evaluate and treat injuries not found on the primary survey. An AMPLE (allergies, medications, past medical history, last meal, environment and events) history should be obtained. Frequent reassessment of the ABCs throughout the emergency department phase of management is necessary. If deterioration occurs, a complete reevaluation of the primary survey should be initiated. Features of the secondary survey and management are listed in Table 33-3.

Pitfalls

The goal of trauma management in the emergency department is to provide life-saving interventions and evaluate for injuries. The tenets of ATLS provide a structured approach to ensure a thorough assessment is performed. Because multiple trauma patients present with a variety of injuries from varying mechanisms, the initial focus is directed at defining the most serious pathology. The emergency physician must be aware of potential pitfalls. Studies from large trauma centers have shown that preventable deaths frequently result from human error and are related to the inability to intubate or secure the airway; delayed control of thoracic, abdominal, and pelvic hemorrhage; and several inpatient factors.\textsuperscript{36,82} Head-injured, unconscious, and intubated patients frequently have injuries that are not identified early in their hospital course.\textsuperscript{83-85} More aggressive diagnostics may be indicated in this subset of patients when history and patient-specific complaints are not obtainable. When cervical radiography is indicated, it is essential that the imaging obtained is complete and adequate. Limited radiographic series and inadequate cervical spine imaging have been shown to result in missed or delayed diagnosis of injuries.\textsuperscript{86}

Radiographic Evaluation

The approach to radiographic evaluation of the trauma patient has changed in recent years. The mantra of C-spine, chest, and pelvic radiographs for all trauma patients has been challenged, and new recommendations continue to emerge. However, in the critically injured patient, imaging of the chest and pelvis and an eFAST exam should be obtained early in the evaluation. These studies provide essential information on possible sources of hemorrhage in either the chest or abdomen or from a pelvic fracture.

Imaging of the cervical spine can usually be delayed; however, in a patient with neurologic findings and persistent moderate hypotension (e.g., 70 mm Hg), neurogenic shock should be considered. A positive finding on C-spine imaging (e.g., fracture, soft tissue swelling, and subluxation) may confirm this if other causes of hypotension have been ruled out. A single cross-table lateral cervical radiograph is not adequate to fully assess the cervical spine; in trauma patients, the sensitivity is too low to rule out fracture.\textsuperscript{87-90}

Cervical spine radiographs may not be necessary in all trauma patients. The NEXUS criteria allows clinical clearance of the cervical spine in patients without posterior midline tenderness, focal neurologic deficit, altered mental status, intoxication, or distracting injury.\textsuperscript{91} The Canadian C-spine rule uses a different set of criteria and, although more complex, has higher specificity and therefore allows the elimination of a higher percentage of unnecessary x-rays.\textsuperscript{92} In a patient with a concerning mechanism of injury or physical examination, computed tomography (CT) scanning is more efficient and effective than plain radiography\textsuperscript{97} and should be considered the primary imaging modality. Plain C-spine radiographs are often inadequate to identify fractures and often miss secondary injury.\textsuperscript{95} In the patient with a low-risk mechanism of injury and no neurologic findings on examination, plain radiography alone may be sufficient to rule out cervical fracture.\textsuperscript{94} If this approach is used, three views of the cervical spine (lateral, anteroposterior, and odontoid) should be obtained.\textsuperscript{95}

Imaging studies of the thoracolumbar spine and extremities can also be delayed until higher priority assessments and interventions are complete. Once the patient has been stabilized, the clinical examination can direct whether additional radiographic examinations are necessary.

Imaging of the thorax early in the evaluation of the trauma patient can give important information about potentially life-threatening injuries. However, the dogmatic “chest x-ray (CXR) for all trauma patients” approach to radiographic evaluation of the chest has undergone some recent challenges. Plain radiography of the chest is considered an acceptable first screening modality. However, in the patient with a significant blunt mechanism of injury, CT scanning may be considered the imaging modality of choice. The sensitivity of CXR alone, even in patients with a normal physical exam, may be too low for use as the primary screening tool to rule out injury to the mediastinum or a blunt aortic dissection.\textsuperscript{96,97} and the results of those radiographs likely do not affect decision-making.\textsuperscript{98} In patients with penetrating thoracic injury, primary CT scan, rather than repeat CXRs, can speed disposition.\textsuperscript{99} Cost and radiation considerations must, of course, be taken into account. Other preliminary evidence suggests that some patients may not require chest imaging.\textsuperscript{100} Ultrasound is gaining favor as the initial screening tool for pneumothorax and hemothorax because it shows better sensitivity and is more rapid than CXR.\textsuperscript{101,102} One possible approach for initial screening of the blunt trauma patient with a significant mechanism of injury could be carried out by thoracic ultrasound to identify life-threatening pleuromediastinal or hemothorax that must be immediately managed, followed by chest CT scan to further elucidate other injuries.

Pelvis radiographs are useful in the severely injured trauma patient. Pelvic fractures can account for significant hemorrhage, and early recognition of fracture and closure of the pelvic space can mitigate hypotension in these patients. Although not validated in large multicenter studies, evidence suggests that pelvic radiographs may be omitted in patients without altered level of consciousness, complaint of pelvic pain, pelvic tenderness on examination, distracting injury, or clinical intoxication.\textsuperscript{103,104} Stable patients undergoing CT scan of the abdomen and pelvis can be further evaluated by bone windows of the CT scan.

As mentioned previously, the eFAST exam should take place early in the evaluation of the trauma patient, ideally as part of the primary survey. A positive scan in hypotensive patients can identify, with good sensitivity, those in need of emergent laparotomy.\textsuperscript{52} In addition, valuable information regarding the presence or absence of pericardial effusion can be obtained. False-negative scans can occur with hollow viscous injuries or solid organ injuries without free fluid.\textsuperscript{105} A normal scan does not necessarily eliminate the need for further abdominal imaging in significantly injured patients. Further discussion and suggested algorithms are found in Chapter 42.

Laboratory Evaluation

Laboratory evaluation of the trauma patient can provide an objective measure of the adequacy of resuscitation. It also provides much needed information for proper transfusion products and the onset of coagulopathy. Finally, it provides baseline information and values for follow-up studies (e.g., tracking hemoglobin values in a patient with a nonoperative splenic injury).

Lactate and base deficit have both been used to measure adequacy of resuscitation in the trauma patient.\textsuperscript{106,107} New non-invasive devices, such as muscle tissue oxygenation and sublingual capnometry, have shown promise in assessing severity of shock and predicting multiorgan dysfunction and mortality.\textsuperscript{108-110} Using one of these objective markers can assist in ensuring proper resuscitation of these patients.
All patients with potentially serious injuries should have blood type and screening done. Cross-matched blood should be immediately ordered for those with apparent serious hemorrhage. As transfusion requirements increase, attention should be paid to the development of coagulopathy. INR and fibrinogen should be followed in these patients. Routine electrolytes, blood urea nitrogen, creatinine, complete blood count, and pregnancy testing (when appropriate) should be obtained as well.

**DISPOSITION**

The emergency department management of the multiple trauma patient is but one critical phase of the spectrum of care. The decision to admit the patient or transfer to a tertiary care facility should be coordinated based on available resources, consultation with the trauma surgeon, and consideration of institutional and regional guidelines.

Ultimate disposition is dictated by a number of factors, including the patient’s condition, the nature of the injury, and the availability of surgeons, subspecialists, and anesthesiologists. Possible dispositions include transfer to the operating room, admission to the surgical service, limited observation in the emergency department, or transfer to another hospital. The level of care and monitoring established in the emergency department should be maintained throughout transfer. All equipment and medications needed for resuscitation and maintenance of vital functions should be available during the transfer, as should qualified personnel to oversee the patient’s care.

In cases of interhospital transfers, all arrangements should be carefully coordinated by physicians at the two institutions. Stabilizing measures are begun before the patient’s transfer, but decompensation in transit should be anticipated. Qualified personnel and necessary resuscitative equipment must accompany the patient. The compelling reason for transferring a patient with life-threatening trauma is the lack of resources or personnel to care for the patient’s particular injuries. Transfer should not be delayed for nonessential diagnostic procedures. All documentation and results of ancillary testing should accompany the patient in transfer.

In certain circumstances, the multiple trauma patient may not need admission or interhospital transfer. The decision to discharge these patients must be evaluated carefully because many traumatic injuries may present in a delayed manner. When discharge is considered, thorough emergency department evaluation is necessary with resources in place to ensure an optimal outcome: surgical consultation where appropriate, attending radiologist support for radiographic image interpretation, and timely, scheduled follow-up as an outpatient.

**SPECIAL CONSIDERATIONS**

The role of emergency department thoracotomy (EDT) has become more selective in order to limit futile resuscitation efforts and minimize risk to providers. Patients with penetrating trauma who have cardiac arrest while in transport or the emergency department are most likely to benefit from EDT. In contrast, cardiac arrest patients with blunt trauma, prolonged cardiopulmonary resuscitation (CPR), or delayed transport times generally have dismal outcomes not altered by EDT. Most institutions have protocols in place outlining criteria for which EDT would be performed. The National Association of EMS Physicians and the ACS Committee on Trauma have published guidelines for withholding or terminating resuscitation efforts in out-of-hospital traumatic cardiac arrest patients. As a result, these guidelines often limit the transport of patients who would not likely benefit from EDT. Patients who may not be transported include any blunt trauma patient without vital signs at the scene, apneic or pulseless penetrating trauma victims without other signs of life, patients receiving more than 15 minutes of CPR, or patients with transport times of more than 15 minutes after arrest. Suggested algorithms for the application of EDT are outlined in Figures 33-2 and 33-3.

When performed, the goal of EDT is to manage rapidly correctable traumatic injuries and allow for transfer to definitive operative intervention. The use of ultrasound should be employed to assist in determining the presence or absence of pericardial effusions and tamponade. When the chest is open, a number of therapeutic measures can be undertaken, depending on the injuries present. After identifying the phrenic nerve, tamponade should be relieved by pericardiotomy. Cardiac injuries are sutured or hemorrhage is controlled with digital pressure or placement of a Foley catheter balloon. Compressing or cross-clamping the pulmonary hilum can control major pulmonary bleeding, but damage to the bronchus is likely to occur and may require repair if the patient survives. The descending aorta is compressed to maximize coronary and cerebral perfusion. The aorta should remain clamped until hemorrhage has been controlled and volume replaced. Open cardiac massage can also be performed.

CHAPTER 34  Trauma in Pregnancy
Kriti Bhatia and Hilarie Cranmer*

■ PERSPECTIVE

Trauma occurs in 6 to 7% of all pregnancies. It is the leading cause of maternal death due to nonobstetric causes, accounting for close to 50% of fatalities in pregnant women. The most common causes of injury in pregnancy, in order of frequency, that result in emergency department (ED) visits are motor vehicle crashes (MVCs), interpersonal violence, and falls. Patients with penetrating injuries present more frequently to EDs in inner city medical centers. Of note, 8% of women, aged 15 to 40, admitted to a trauma center do not yet know they are pregnant. Commonly used thresholds of fetal viability are an estimated gestational age of 24 to 26 weeks or an estimated fetal weight of 500 g. Only viable fetuses are monitored, because no obstetric intervention will alter the outcome with a previable fetus. Counseling on proper seatbelt and alcohol use and screening for interpersonal violence may help to reduce the morbidity and mortality rates for pregnant patients. Although the essential principles of trauma management remain unchanged in the pregnant patient, a number of special points need to be considered. Pregnancy causes alterations in physiology and anatomy that affect multiple organ systems. Although there are two lives involved, maternal life takes priority.

■ PRINCIPLES OF DISEASE—CHANGES OF PREGNANCY

Physiology

Cardiovascular

The normal cardiovascular changes of pregnancy can alter the presentation of shock and vascular events (Table 34-1).

Some Alterations Mimic Shock. Blood pressure declines in the first trimester, levels out in the second trimester, and then returns to nonpregnant levels during the third trimester. The decline in systole is small, 2 to 4 mm Hg, whereas diastole falls 5 to 15 mm Hg. Heart rate increases in pregnancy but does not rise by more than 10 to 15 beats per minute above baseline (mean of approximately 90 beats/min). Blood flow to the uterus increases from 60 mL/min before pregnancy to 600 mL/min at term. This hyperdynamic state is needed to maintain adequate oxygen delivery to the fetus. Because the mother’s total circulating blood volume flows through the uterus every 8 to 11 minutes at term, this organ can be a major source of blood loss when injured. By the third trimester there is also marked venous congestion in the pelvis and lower extremities, increasing the potential for hemorrhage from both bony and soft tissue pelvic injuries.

Compression of the lower abdominal venous system by the gravid uterus increases peripheral venous pressure and volume in the legs, creating the potential for brisk blood loss from leg wounds.

This alteration can play an important role in procedures that may be necessary for maternal resuscitation, such as central venous catheter placement.

Alterations That May Mask Hypovolemic Shock. Blood volume gradually increases during pregnancy, starting at 6 to 8 weeks’ gestation, to as much as 45% above normal, peaking at 32 to 34 weeks’ gestation. Blood volumes become increasingly larger for multigravidas, twins, triplets, and quadruplets. With this increased circulatory reserve, clinical signs of maternal hypotension from acute traumatic bleeding may be delayed.

Some Alterations Can Exacerbate Traumatic Bleeding. By the beginning of the second trimester and throughout the remaining pregnancy, cardiac output is increased 40%, to 6 L/min. Blood flow to the uterus increases from 60 mL/min before pregnancy to 600 mL/min at term. This hyperdynamic state is needed to maintain adequate oxygen delivery to the fetus. Because the mother’s total circulating blood volume flows through the uterus every 8 to 11 minutes at term, this organ can be a major source of blood loss when injured. Pulmonary

The term pregnant woman has a significantly reduced oxygen reserve. This effect comes from a 20% reduction in functional residual capacity caused by diaphragm elevation and a 15% increase in oxygen consumption related to the growing fetus, uterus, and placenta. Archer and Marx observed that mean arterial oxygen tension dropped by 29% in term pregnant women during 60 seconds of apnea but just 11% in non-pregnant women. Labor accelerates this decline by a further 7%.

Additionally, minute ventilation increases, leading to hypocapnea. Therefore, an arterial partial pressure of carbon dioxide (PaCO₂) of 35 to 40 mm Hg may indicate inadequate ventilation and impending respiratory decomposition in the pregnant patient. At signs of respiratory compromise or hypoxia, endotracheal intubation should be considered, as maternal hypoxia rapidly leads to fetal hypoxia, distress, and possibly demise. There are no contraindications to rapid sequence intubation during pregnancy. Bag-valve-mask ventilation is more difficult in the pregnant patient.

Gastrointestinal

Gastroesophageal sphincter response is reduced in pregnancy and gastrointestinal motility is decreased, both of which increase the possibility of aspiration during reduced levels of consciousness and intubation. The stomach’s increased acid production in pregnancy makes aspiration more ominous than usual. Therefore early gastric decompression should be considered under appropriate circumstances.

Anatomic Changes in Pregnancy

The uterus remains an intrapelvic organ until approximately the 12th week of gestation. It reaches the umbilicus by 20 weeks and the costal margins by 34 to 36 weeks. It grows from a 7-cm, 70-g organ to a 36-cm, 1000-g structure at term. As a result of this growing mass, the normal anatomic location and function of multiple structures are altered.

The diaphragm progressively rises an extra 4 cm in pregnancy with compensatory flaring of the ribs. Pneumothorax may be exacerbated and tension pneumothorax can develop more quickly in pregnancy because of this diaphragm elevation, combined with pulmonary hyperventilation. For thoracostomies done in the third trimester, the chest tube should be placed one or two interspaces higher than the usual fifth interspace site to allow for diaphragm elevation.

Abdominal viscera are pushed upward by the enlarging uterus, resulting in altered pain location patterns. The gravid uterus itself tends to protect abdominal organs from trauma but substantially increases the likelihood of bowel injury with penetrating trauma to the upper abdomen. Conversely, the upward displacement of the bowel makes it less susceptible to blunt trauma. The stretching of the abdominal wall modifies the normal response to peritoneal irritation. Therefore, expected muscle guarding and rebound can be progressively blunted as pregnancy approaches term, despite significant intra-abdominal bleeding and organ injury, another factor that may lead to underestimation of the extent and gravity of maternal trauma.

Total weight for the gravid uterus and its contents typically reaches 4500 g. In the first trimester, the bony pelvis shields the uterus. After the third month, the uterus rises out of the pelvis and becomes vulnerable to direct injury. The bladder is also displaced into the abdominal cavity beyond 12 weeks’ gestation, thereby becoming more vulnerable to injury. Like the uterus, the bladder becomes hyperemic, and injury may lead to a marked increase in blood loss compared with similar injury in a nonpregnant patient.

Imaging studies may show ureteral dilation that can be physiologic secondary to smooth muscle relaxation or caused by compression from the gravid uterus. Thus hydronephrosis is not necessarily pathologic. The ligaments of the symphysis pubis and sacroiliac joints are loosened during pregnancy. As a result, a baseline diastasis of the pubic symphysis may exist that can be mistaken for pelvic disruption on a radiograph.

Changes in Laboratory Values with Pregnancy

The physiologic anemia of pregnancy, resulting from a 48 to 58% increase in plasma volume and only an 18% increase in red blood cells, causes hematocrits of 32 to 34% by the 32nd to 34th week. Despite the lower hematocrit, there is actually an overall increase in oxygen-carrying capacity because of an increased total red blood cell mass.

Placental progesterone directly stimulates the medullary respiratory center, producing a PaCO₂ of 30 mm Hg from the second trimester until term. The subsequent compensatory lowering of serum bicarbonate to 21 mEq/L slightly reduces blood-buffering capacity for stress situations. A PaCO₂ of 40 mm Hg in the latter half of pregnancy reflects inadequate
ventilation and potential respiratory acidosis that could precipitate fetal distress.

Electrocardiographic changes include a left-axis shift averaging 15 degrees, caused by diaphragm elevation. Consequently, flattened T waves or Q waves in leads III and augmented voltage unipolar in left foot lead may be seen.

### Clinical Features of Trauma in Pregnancy

#### Blunt and Penetrating Trauma

The findings of the physical examination in the pregnant woman with blunt trauma are not reliable in predicting adverse obstetric outcomes. However, risk factors that significantly predictive of contractions or preterm labor include gestational age greater than 35 weeks, assaults, and pedestrian collisions. In gravid patients, penetrating trauma of the abdomen has an increased likelihood of causing injuries of the bowel, liver, or spleen.

Fetal mortality rates range between 4 and 40% after maternal trauma, with most likely causes of fetal death occurring from placental abruption, maternal shock, and maternal death, in order of decreasing incidence. Risk factors significantly predictive of fetal death included ejections, motorcycle and pedestrian collisions, maternal death, maternal tachycardia, abnormal fetal heart rate, lack of restraints, and an Injury Severity Score greater than 9.9

Unbelted or improperly restrained pregnant women are twice as likely to experience excessive maternal bleeding, and fetal death is three times more likely to occur.19,20 For low-to moderate-severity crashes (constituting 95% of all MVCs), proper restraint use, with or without air bag deployment, generally leads to acceptable fetal outcomes. For high-severity crashes, even proper restraint does not improve fetal outcome.21

Pregnant crash-test-dummy trials show that improper placement of the lap belt over the pregnant abdomen causes a three- to fourfold increase in force transmission through the uterus. The lowest force transmission readings through the uterus occur when a three-point seat belt is used properly. For correct position, the lap belt should be placed under the gravid abdomen, snugly over the thighs, with the shoulder harness off to the side of the uterus, between the breasts and over the midline of the clavicle.22 Women who receive information on seat belt use during pregnancy from a health care worker are statistically more likely to use seat belts and to use them properly than uninformed controls.23

#### Interpersonal Violence

Although it has been previously documented that intimate partner violence against women affects one in four U.S. women, and numerous health consequences have been associated with being a victim of such violence, a recent study by Silverman and colleagues conclusively demonstrates that physical abuse from husbands or boyfriends compromises a woman’s health during pregnancy, as well as her likelihood of carrying a child to term and the health of her newborn.24 Women experiencing abuse in the year prior to or during a recent pregnancy were 40 to 60% more likely than nonabused women to report high blood pressure, vaginal bleeding, severe nausea, kidney or urinary tract infections, and hospitalization during this pregnancy. Abused women were 37% more likely to deliver preterm, and children of abused women were 17% more likely to be born underweight. These conditions pose grave health risks to newborns, and children born to abused mothers were over 30% more likely than other children to require intensive care at birth.24-27 Physicians detect only 4 to 10% of cases, which supports the need for routine screening for interpersonal violence in pregnant patients.27

#### Falls

Falls become more prevalent after the 20th week of pregnancy.2 Protuberance of the abdomen, loosening of pelvic ligaments, strain on the lower back, and fatigability contribute to this problem. In a given pregnancy, about 2% of pregnant women sustain repeated direct blows to the abdomen because of falling more than once. Although repeated falls often trigger premature contractions, they seldom result in immediate labor and delivery.28

#### Penetrating Trauma

The gravid uterus alters injury patterns to the mother. There is an increased probability of harm (approaching 100%) to the bowel, liver, or spleen if the entrance of the penetrating object is in the upper abdomen. When the entry site is anterior and below the uterine fundus, visceral injuries are less likely. Although the enlarging uterus can act as a shield against intra-abdominal injuries in the mother, it makes the fetus more susceptible to injury. Awwad and colleagues observed a 67% fetal death rate from penetrating trauma to the uterus but a lower fetal death rate (38%) for maternal injuries above the uterus.29

#### Fetal Injury

Pregnancy does not alter rates of maternal mortality caused by trauma. However, trauma is associated with a high risk for fetal loss. When the mother suffers a severe level of injury, poor fetal outcome is predicted by maternal hypotension and acidosis (hypoxia, lowered pH, lowered bicarbonate) and a fetal heart rate of less than 110 beats per minute.6,7,10,34 When the mother suffers life-threatening injuries, there is a 40% chance of fetal demise, compared with a less than 2% chance in cases of non–life-threatening maternal injuries. Maternal age and gestational age may also be important factors in determining fetal outcome.35

For women with less severe trauma, fetal outcome is not predicted by maternal vital signs, abdominal tenderness, blood tests, or ultrasonography (US) results. Only cardiotocographic monitoring for a minimum of 4 hours is useful in predicting fetal outcome.3

Fetal in utero fetal injuries from blunt trauma usually involve intracranial hemorrhage and skull fractures. Such head injury is often secondary to fractured maternal pelvic bones striking the fetal skull due to vertex lie.36,37 Pelvic and acetabular fractures during pregnancy are associated with a high maternal (9%) and a higher fetal (38%) mortality rate.38 With penetrating trauma, gunshot wounds to the uterus are associated with a high incidence of fetal injury (59–89%) and fetal mortality (41–71%).40 Stab wounds to the uterus can produce 93% morbidity and 50% mortality rates, respectively, to the fetus.40

#### Placental Injury

In blunt trauma, 50 to 70% of all fetal losses result from placental abruption.41,42 It is the leading cause of fetal death after blunt trauma.

Placental separation results when the inelastic placenta shears away from the elastic uterus during sudden deformation of the uterus. Because deceleration forces can be as damaging
to the placenta as direct uterine trauma, abruption can occur with little or no external sign of injury to the abdominal wall.\textsuperscript{45} Because all gas exchange between the mother and fetus occurs across the placenta, abruption inhibits the flow of oxygen to the fetus and causes in utero CO\textsubscript{2} accumulation. Such hypoxia and acidosis can lead to fetal distress.\textsuperscript{13} Sustained uterine contractions induced by intraterine hemorrhage also inhibit uterine blood flow, further contributing to fetal hypoxia.\textsuperscript{44}

The diagnosis of abruption is a clinical one, and ultrasonography and the Kleihauer-Betke test are of limited value.\textsuperscript{25} Classical clinical findings of abruption may include vaginal bleeding, abdominal cramps, uterine tenderness, maternal hypovolemia (up to 2 L of blood can accumulate in the gravid uterus), or a change in the fetal heart rate. However, in some trauma studies, as many as 63\% of cases showed no evidence of vaginal bleeding.\textsuperscript{46}

The most sensitive indicator of placental abruption is fetal distress. Hence, prompt fetal monitoring is a very important assessment technique in trauma during pregnancy. There is also a close linkage of abruption to uterine activity. One study reported that if 12 or more contractions occurred in any hour of a 4-hour cardiotocographic monitoring period, the risk of abruption was 14\%; abruption did not occur in this study if contractions occurred less than once every 10 minutes.\textsuperscript{3} Ultrasound (US) is less than 50\% accurate as a first-line test in detecting placental abruption.\textsuperscript{3,47} If the abruption bleeds externally, not enough blood collects to be seen sonographically. Even with significant intraterine blood accumulation, accurate US diagnosis may be difficult because of placental position (i.e., posterior) and confounding uterine or placental structural conditions.\textsuperscript{48}

Placental abruption is associated with an overall 8.9-fold increased risk of stillbirth (20 weeks) and a 3.9-fold increased risk of preterm delivery (before 37 weeks). The extent of placental separation affects stillbirth rates. At 50\% separation there is a fourfold increase of stillbirth and a more profound 31.5-fold increased risk of stillbirth at 75\% separation. The risk of preterm delivery is substantially increased with even mild abruptions; a 25\% separation carries a 5.5-fold increased risk of preterm.\textsuperscript{49}

When mother and fetus are stable, expectant management can be tried for partial placental abruptions of less than 25\%. This usually applies to fetuses of less than 32 weeks’ gestation in whom the likelihood of morbidity and mortality associated with prematurity makes delivery management risky. Expectant care in stable patients may allow further fetal maturation and improved outcome. Metzger and associates recommended intervention if the fetus is older than 32 weeks’ gestation because the risk of further placental separation outweighs the benefit of further fetal maturation.\textsuperscript{48} If expectant management is pursued, close maternal and fetal monitoring is needed to ensure the well-being of both patients. The ability to perform an immediate cesarean section is necessary because there may be little time between the appearance of fetal distress from further placental separation and the occurrence of fetal death.\textsuperscript{51}

Women with placental abruption are more likely to have coagulopathies than those without abruption.\textsuperscript{51} The injured placenta can release thromboplastin into the maternal circulation, resulting in disseminated intravascular coagulation, whereas the damaged uterus can disperse plasminogen activator and trigger fibrinolysis.\textsuperscript{44} The precipitation of disseminated intravascular coagulation is directly related to the degree of placental separation. Severe clotting disorders rarely occur unless separation of the placenta is significant enough to result in fetal demise.\textsuperscript{55}

### Uterine Injury

The most common obstetric problem caused by maternal trauma is uterine contractions.\textsuperscript{3,44} Myometrial and decidual cells, irritated by contusion or placental separation, release prostaglandins that stimulate uterine contractions. Progression to labor depends on the extent of uterine damage, the amount of prostaglandins released, and the gestational age of the pregnancy. The routine use of tocolytics for premature labor has come under question because 90\% of contractions stop spontaneously.\textsuperscript{3} Contractions that are not self-limited are often induced by some pathologic condition, such as underlying placental abruption, which is a contraindication to tocolytic therapy. Others consider this contraindication relative and have used tocolysis successfully with careful evaluation and intensive monitoring to continue the pregnancy and enhance fetal maturity.\textsuperscript{53} The option to use tocolytics ends when cervical dilation reaches 4 cm.

Uterine rupture is a rare event. It is most often caused by severe vehicular crashes in which pelvic fractures strike directly against the uterus. There have been a few reports of uterine rupture from stab wounds and gunshot injuries.\textsuperscript{50} Maternal shock, abdominal pain, easily palpable fetal anatomy caused by extrusion into the abdomen, and fetal demise are typical findings on examination. Diagnosing uterine rupture can be difficult. A fractured liver or spleen can produce similar signs and symptoms of peritoneal irritation, hemoperitoneum, and unstable vital signs. Optimal treatment, between suturing the tear or performing a hysterectomy, depends on the extent of uterus and uterine vessel tears and the importance of future childbearing.

### Diagnostic Strategies

#### Radiography

##### Plain Radiographs

Adverse effects are unlikely at less than 5 to 10 radiation-absorbed doses (rad). Less than 1\% of trauma patients are exposed to more than 3 rad. Sensitivity to radiation is greater during intrauterine development than at any other time of life, especially in the first trimester (i.e., when the embryo undergoes organogenesis in weeks 2–9). However, the risk to the fetus of a 1-rad (1000 mrad) exposure, approximately 0.003\%, is thousands of times smaller than the spontaneous risks of malformations, abortions, or genetic disease.\textsuperscript{52} Studies show that intrauterine exposure to 10 rad causes no significant increase in congenital malformations, intrauterine growth retardation, or miscarriage but is associated with a small increase in the number of childhood cancers.\textsuperscript{54-60} Pathologic conditions more readily appear with intrauterine radiation doses of 15 rad. At 15 rad there is approximately a 6\% chance that the fetus could experience severe mental retardation, a less than 3\% chance of developing childhood cancer, and a 15\% chance of the having a small head, although this does not necessarily affect normal cerebral function.\textsuperscript{54}

Providing information on radiation exposure from diagnostic radiographs is difficult. The individual amount of fetal dosage may vary by a factor of 50 or more, depending on the equipment used, technique, number of radiographs done in a complete study, maternal size, and fetal-uterine size. In general, coned x-ray beams aimed more than 10 cm away from the fetus are not harmful.\textsuperscript{62}

Diagnostic radiographic studies should be performed with regard for fetal protection, but necessary diagnostic studies should not be withheld out of concern for fetal radiation exposure. When appropriate, fetal irradiation should be minimized...

Computed Tomography and Magnetic Resonance Imaging Scans

CT and, increasingly, magnetic resonance imaging (MRI) studies are used in evaluating abdominal trauma in pregnancy. If US is indeterminate and the patient’s condition is stable, CT and MRI have the potential to identify specific organ damage. They are particularly useful in assessing penetrating wounds of the flank and back. CT can miss diaphragm and bowel injuries. Both of these studies generally lack portability, and trauma patients may have to be taken from the closely monitored environment of the ED to a distant room.

Radiation from CT is a concern in the pregnant trauma patient. However, with shielding, fetal exposure from head and chest CT scans can be kept below an acceptable 1-rad limit. CT of the abdomen above the uterus can be done with less than 3 rad of exposure to the fetus. Pelvic CT, centered over the fetus, produces a more prohibitive 3- to 9-rad dose. Fortunately, spiral CT can reduce radiation dosage by a further 14 to 30%. Radiation exposure ultimately depends on the patient, scanner, and technique used in performing the study (see Table 34-2). MRI scanners use no radiation and cause no fetal disease or disability.

Special Procedures

Diagnostic Peritoneal Lavage

In unstable trauma patients with equivocal or negative findings on US, DPL can be done quickly and safely in any trimester by an open technique above the uterus. Blunt trauma studies indicate that the gravid uterus does not compartmentalize intraperitoneal hemorrhage and does not reduce the accuracy of DPL for selecting patients who need operative intervention for intra-abdominal bleeding. DPL is limited in detecting bowel perforations and does not assess retroperitoneal and intrauterine pathology.

Management

As with any trauma, advance notification and preparation can be helpful. Depending on mechanism, maternal condition, and gestational age, the emergency physician should consider early notification or consultation with an obstetrician, neonatologist, or pediatrician (or all three). A fetal monitor, portable US, and neonatal resuscitation equipment should be available in the E.D. 74

Maternal Resuscitation

Primary Survey

The primary survey focuses on the mother. However, because two patients are present, it is reasonable also to gather preliminary information about the fetus in the primary survey (Fig. 34-1).

Airway and Breathing. Oxygen therapy should be instituted early. Because of reduced oxygen reserve and increased oxygen consumption, the traumatized pregnant woman can quickly become hypoxic. The fetus is very vulnerable to any reduction in oxygen delivery. Animal studies show that severe hypoxia causes a 30% reduction in uterine blood flow. Therefore, supplemental oxygen should be continued throughout maternal resuscitation and evaluation.

A secure airway is critical to an optimum outcome. Not only does it enable proper oxygenation but it negates the higher risk of aspiration in pregnancy. Rapid sequence intubation is
With trauma in pregnancy, the primary survey can be modified to assess uterine size and the presence of fetal heart tones. Uterine size, measured from the symphysis pubis to the fundus, is the quickest means of estimating gestational age. This distance in centimeters equals the gestational age in weeks (e.g., 24 cm = 24 weeks), which allows some early indication of fetal viability if delivery is necessary (Fig. 34-2). Usually, 24 to 26 weeks is used as the cutoff point for fetal viability (Table 34-3). As a rough guide, the fetus is potentially viable when the dome of the uterus extends beyond the umbilicus. Fetal heart tones can be detected by auscultation at 20 weeks' gestation or by Doppler probe at 10 to 14 weeks. If either the uterus is less than 24 cm in size or fetal heart tones are absent, the pregnancy is probably too early to be viable, and treatment is directed solely at the mother.

**Circulation.** Any time significant maternal injury is suggested by the mechanism of injury or clinical findings, early IV access for volume resuscitation is indicated. Maternal blood pressure and heart rate are not consistently reliable predictors of fetal and maternal well-being. Because of an expanded circulating volume, the mother can be bleeding but not show early signs of hypotension. The uterus is not a critical organ, and its blood flow is markedly reduced when the maternal circulation must be maintained. As a result, after an acute blood loss, uterine blood flow can be decreased 10 to 20% while maternal blood pressure remains normal. Consequently, the mother who presents with borderline stability probably already has a jeopardized fetus. When traditional signs of shock appear, fetal compromise can be far advanced. Vasopressors should be avoided because they produce fetal distress by further decreasing uterine blood flow.

Beyond 20 weeks’ gestation, the patient should be tilted to approximately 30 degrees to the left when on a backboard or should have the right hip elevated, unless otherwise precluded by right-sided injuries. This reduces the compression on the inferior vena cava caused by the gravid uterus. Tilting to the right is less effective in removing the uterus from the inferior vena cava; so consider manually displacing the uterus upward and leftward as discussed earlier.

For severe injuries, a CVP line is helpful in assessing cardiac preload. CVP pressures decline as pregnancy progresses because of inferior vena caval compression by the gravid uterus. Therefore, correction to nonpregnant normal pressures may be unnecessary. Instead, it is more valuable to focus on trends of how the CVP responds to fluid challenges. A Foley catheter for measuring urine output provides further information on circulatory volume status.

With trauma in pregnancy, the primary survey can be modified to assess uterine size and the presence of fetal heart tones. Uterine size, measured from the symphysis pubis to the fundus, is the quickest means of estimating gestational age. This distance in centimeters equals the gestational age in weeks (e.g., 24 cm = 24 weeks), which allows some early indication of fetal viability if delivery is necessary (Fig. 34-2). Usually, 24 to 26 weeks is used as the cutoff point for fetal viability (Table 34-3). As a rough guide, the fetus is potentially viable when the dome of the uterus extends beyond the umbilicus. Fetal heart tones can be detected by auscultation at 20 weeks’ gestation or by Doppler probe at 10 to 14 weeks. If either the uterus is less than 24 cm in size or fetal heart tones are absent, the pregnancy is probably too early to be viable, and treatment is directed solely at the mother.

**Secondary Survey**

The secondary survey involves a detailed examination of the patient but is also modified to gather additional information about the maternal abdomen and the fetus. Physical examination of the abdomen, frequently unreliable in the nonpregnant patient, is more inaccurate with changing organ position, abdominal wall stretching in advancing pregnancy, and uterine

contraction pains. Still, information can be gathered about uterine tenderness, contraction frequency, and vaginal bleeding.

Pelvic examination begins with sterile speculum examination to allow direct visualization to enable detection of possible trauma in the genital tract, the degree of cervical dilation, and the source of any observed vaginal fluid. Vaginal bleeding suggests placental abruption, and a watery discharge suggests rupture of the membranes. If a vaginal fluid sample placed on a slide dries and crystallizes in a ferning pattern, it is amniotic fluid and not urine. Cervical cultures for group B streptococci, Neisseria gonorrhoeae, and Chlamydia should be obtained if there is evidence of amniotic fluid leak. Bimanual examination should be limited to assessing for pelvic bone injury or progression of advanced labor. This examination is preferably performed by an obstetrician. If the mechanism of injury is significant enough and the fetus is judged to be viable, it is strongly preferred that an obstetrician be involved in the treatment.

**Fetal Evaluation**

Fetal evaluation in the secondary survey focuses on the fetal heart rate and detection of fetal movement. When the presence of fetal heart tones has been confirmed, intermittent monitoring of fetal heart rate is sufficient for the viable fetus. If the fetus is viable (i.e., 24 weeks or more), continuous external monitoring should be initiated quickly and maintained throughout all diagnostic and therapeutic procedures. Such monitoring can also benefit the mother because fetal hemodynamics are more sensitive to decreases in maternal blood flow and oxygenation than are most measures of the mother. Fetal distress can be a sign of occult maternal distress. Signs of fetal distress include an abnormal baseline rate, decreased variability of heart rate, and fetal decelerations after contractions.

The normal fetal heart rate ranges between 120 and 160 beats per minute. Rates outside or trending toward these limits are ominous. Heart rate variability has two components. Beat-to-beat variability measures autonomic nervous function, whereas long-term variability indicates fetal activity. Heart rate variability increases with gestational age. The loss of beat-to-beat and long-term variability warns of fetal central nervous system depression and reduced fetal movement caused by fetal distress (Fig. 34-3).

Late decelerations are an indication of fetal hypoxia. These decelerations are relatively small in amplitude and occur after the peak or conclusion of a uterine contraction. By comparison, early decelerations are larger, occur with the contraction, and recover to baseline immediately after the contraction. Early decelerations may be vagally mediated when uterine contractions squeeze the fetal head, stretch the neck, or compress the umbilical cord. Variable decelerations are large, occur at any time, and are possibly caused by umbilical cord compression (Fig. 34-4).

**Laboratory**

Besides routine trauma blood work, emergency laboratory tests should include a blood type with Rh status. In apparently stable pregnant patients, a low serum bicarbonate level may indicate occult maternal shock. Interpretation of bicarbonate results must consider that the normal bicarbonate level is 21 mEq/L in the later stages of pregnancy due to respiratory alkalosis. Arterial blood gases can allow detection of maternal hypoxia and acidosis, whereas pulse oximetry can be used to monitor oxygen saturation. Coagulation studies should be obtained for patients with multisystem trauma or when the diagnosis of placental abruption is considered. The main difference between the nonpregnant trauma patient and the pregnant trauma patient’s laboratory workup is the need to determine Rh status and quantitative β-hCG, if indicated based on mechanism; besides this, the physician should order any and all laboratory tests that would be ordered for any trauma patient.

**Kleihauer-Betke Test and Fetomaternal Hemorrhage**

Fetomaternal hemorrhage (FMH), the transplacental bleeding of fetal blood into the normally separate maternal circulation, is a unique complication of pregnancy. The reported incidence

---

**Figure 34-3.** Types of fetal heart rate variability. bpm, beats per minute; FHR, fetal heart rate; UA, uterine activity.
of FMH after trauma is 8 to 30% (with a range of 2.5–11.5 mL of blood) compared with 2 to 8% (range of 0.1–8 mL) for control studies. MVCs, anterior placental location, and uterine tenderness are associated with an increased risk of FMH, but gestational age is not.\(^3,7\) Massive fetomaternal transplacental hemorrhage causes alloimmunization in Rh incompatibility but also endangers the fetus by severe fetal anemia and resulting fetal distress and possible exsanguination. ABO incompatibility causes less severe disease.

In theory, it is possible that trauma can result in FMH as early as the fourth week of gestation, when the fetal and placental circulations first form. In practice, FMH is usually of more concern after 12 weeks’ gestation, when the uterus rises above the pelvis and becomes susceptible to direct trauma.\(^3\)

The Kleihauer-Betke test identifies fetal cells in a maternal blood sample. Most laboratories screen for FMH of 5 mL or more. Unfortunately, the amount of FMH sufficient to sensitize most Rh-negative women is well below this 5-mL sensitivity level. Therefore, all Rh-negative mothers who have a history of abdominal trauma should receive one prophylactic dose of Rhesus immune globulin (RhIG). In the first trimester, one 50-µg dose is used because total fetal blood volume is only 4.2 mL by 12 weeks’ gestation and a 50-µg dose covers 5 mL of bleeding. During the second and third trimesters, a 300-µg dose of RhIG is given, which protects against 30 mL of FMH. Beyond 16 weeks’ gestation, the total fetal blood volume reaches 30 mL, so it is quite possible that massive FMH may exceed the efficacy of one 300-µg dose of RhIG. Therefore, it is unlikely that a Kleihauer-Betke test is useful in the treatment of severely injured pregnant trauma patients.

Trauma patients at risk for massive FMH present with major injuries or abnormal obstetric findings, such as uterine tenderness, contractions, or vaginal bleeding. Less than 1% of all pregnant trauma patients and only 3.1% of major trauma cases exceed the coverage of one 300-µg RhIG dose.\(^3\)

Because RhIG can effectively prevent Rh isoimmunization when administered within 72 hours of antigenic exposure, the results of the Kleihauer-Betke test are not immediately needed in the ED.

**Mother Stable, Fetus Stable**

Minor trauma does not necessarily exempt the fetus from significant injury. It is estimated that 1 to 3% of all minor trauma results in fetal loss, typically from placental abruption.\(^7\) Therefore, once the traumatized mother is stabilized, the focus of care is directed toward the fetus. For the viable fetus (greater than 24 weeks’ gestation), monitoring is the next step. Monitoring must be continuous and should be maintained throughout all diagnostic and therapeutic actions. Because direct impact is not necessary for fetoplacental pathology to occur, the mother with no obvious abdominal injury still needs monitoring.

The recommended 4 hours of cardiotocographic observation of the viable fetus should be extended to 24 hours if, at any time during the first 4 hours, there are more than three uterine contractions per hour, uterine tenderness persists, results on a fetal monitor strip are worrisome, vaginal bleeding occurs, the membranes rupture, or if any serious maternal injury is present. In Pearlman’s study, all cases of placental abruption after maternal trauma were detected within the first 4 hours of monitoring.\(^3\) These mothers typically had more than 12 uterine contractions per hour. Although 70% of patients required admission beyond the 4-hour observation period, all patients who were discharged at the end of the 4-hour or 24-hour monitoring periods had subsequent live births.

On release from the hospital, the mother should be instructed to record fetal movements during the next week. If fewer than four movements per monitored hour are noted, the patient should see her obstetrician immediately and a nonstress test should be performed. The occurrence of preterm labor, membrane rupture, vaginal bleeding, or uterine pain also necessitates prompt reevaluation. Serial US and fetal heart rate tests should be performed on viable fetuses a few days after all trauma episodes and periodically throughout the remaining portion of the pregnancy to monitor fetal well-being.

**Mother Stable, Fetus Unstable**

Fetal death rates following maternal trauma are three to nine times higher than maternal death rates.\(^9\) If a viable fetus
remains in distress despite optimization of maternal physiology, cesarean section should be performed.

Although fetal viability is first reached at 24 weeks, the ultimate determination of the age of fetal viability is the level of neonatal care provided by the intensive care nursery unit in each hospital or accessible regional facility. Note that determining gestational age for fetuses less than 29 weeks is difficult. Even with the best US criteria, unless the time of conception is known exactly, the assignment of gestational age is subject to 1 to 2 weeks of uncertainty. Emergency decisions on fetal viability are, therefore, made on the basis of the best gestational age information available.

Morris and colleagues found that the presence of fetal heart tones is an important survival marker for fetuses about to undergo emergency cesarean section. No infant survives if there is no fetal heart tone before emergency cesarean section commences. If fetal heart tones are present and the gestational age is 26 weeks or more, then infant survival rate is 75%. Sixty percent of fetal deaths result from underuse of cardiotocographic monitoring and delayed recognition of fetal distress.

Besides fetal distress, other reasons for a cesarean section include uterine rupture, placental rupture with significant vaginal bleeding, fetal malpresentation during premature labor, and situations in which the uterus mechanically limits vaginal bleeding. Fetal demise without any of the aforementioned conditions is not an indication for cesarean section.

Mother Unstable, Fetus Unstable

If the mother’s condition is critical, primary repair of her wounds is the best course. This may apply even when the fetus is in distress because a critically ill mother may not be able to withstand an additional operative procedure such as cesarean section, which prolongs laparotomy time and increases blood loss by at least 1000 mL. The best initial action on behalf of the fetus is early restoration of normal maternal physiology. If it is felt that the unstable mother can tolerate an emergency cesarean section, it can be attempted for the distressed, viable fetus.

As with nonpregnant patients, operative intervention for blunt trauma and above-the-uterus stab wounds is dictated by clinical findings and diagnostic testing results. Above-the-uterus intraperitoneal gunshot wounds should be explored.

There is little evidence to support a definitive management strategy for penetrating trauma to the gravid uterus. In situations of a hemodynamically stable mother, expectant management has been recommended. However, no prospective study has verified this. Damage to the uterus alone can be quite devastating because of its increased circulation. Meizner and Potashnik reported a shrapnel injury to only the uterus in a case in which an initial normal examination quickly changed to a hypotensive emergency. At celiotomy, 1000 mL of blood was found in the abdomen from a perforated corner injury to the uterus. Without exploration it is impossible to know the occurrence, size, or depth of uterine penetration, and there are no guidelines indicating whether a uterine wound can be left unsutured without incurring an increased risk of infection or delayed uterine rupture. Laparotomy or laparoscopy seems to be the safest means of managing penetrating uterine wounds because missed maternal injuries can quickly compromise the fragile fetus.

Perimortem Cesarean Section

Restoration of maternal and thus fetal circulation is the optimal goal. However, extended and exclusive attention to the mother in cardiopulmonary arrest may prevent recovery of a potentially viable fetus. During maternal resuscitation, adequate oxygenation, fluid loading, and a 30-degree left tilting position should be tried to determine whether maternal circulation can be improved. If there is no response to advanced cardiac life support, a decision for perimortem cesarean section must be made. If there are no fetal heart tones, a cesarean section is not warranted.

Perimortem cesarean section in the ED should be performed if uterine size exceeds the umbilicus and fetal heart tones are present. Time since maternal circulation ceased is the critical factor in fetal outcome. Published reports from more than 20 years ago support, but fall far from proving, that perimortem cesarean delivery should be initiated within 4 minutes if no pulse to obtain cardiac return by 5 minutes. Beyond 20 minutes, there is virtually never survival or favorable neurologic outcome for either mother or fetus.

In the event of maternal cardiopulmonary arrest, perimortem cesarean section is indicated. The most experienced physician, preferably an obstetrician, should perform the procedure. However, this task ultimately may fall to the emergency physician or trauma surgeon, given the time constraints of the situation. A pediatric consultation should be obtained emergently. While continuing CPR, a “classic midline vertical incision is made, using a large scalpel, extending from the epigastrum to the symphysis pubis and carried through all layers to the peritoneal cavity. A vertical incision is then made in the anterior uterus from the fundus to the bladder reflection. Assistants and other surgical instruments (e.g., clamps, retractors) are helpful but not required. If, when the uterus is entered, an anterior placenta is encountered, it should be incised in order to reach the fetus. The cord should be promptly clamped and cut following delivery of the child.” Maternal revival after delivery of the fetus is reported in a few perimortem circumstances, presumably because vena caval compression is relieved.

DISPOSITION

Any pregnant woman at 24 or more weeks of gestation who has suffered blunt body trauma should undergo at least 4 hours of fetal monitoring even if she looks well. Other admission and operative criteria are similar for pregnant and nonpregnant trauma patients. The emergency physician must always consider the stability of the mother and the viability of the growing fetus when making management and disposition decisions.

MISCELLANEOUS

Tetanus toxoid and immune globulin have no detrimental effect on the fetus. Proper immunization of pregnant women decreases the incidence of neonatal tetanus because the tetanus antibody crosses the placenta.

Electrical flow that bypasses the fetus has little effect on the pregnancy. Maternal elective and emergent cardioversion has been performed safely for cardiac dysrhythmias in all three stages of pregnancy. Energies up to 300 watt-seconds have been used without affecting the fetus or inducing premature labor. Cullhead reported no disruption of a monitored fetal heart rhythm during maternal cardioversion with 80 and 200 watt-seconds. Although the amount of energy reaching the fetal heart is thought to be small, the fetal heart should be monitored during cardioversion.
KEY CONCEPTS

- Management of life- and limb-threatening injury in the mother comes first.
- Even in the noninjured pregnant patient, the fetus is at increased risk of morbidity and mortality.
- The fetus is viable at 24 weeks’ gestation. A fetus is estimated to be viable if the fundus is at or above the umbilicus.
- When assessing the injured pregnant patient, it is important to keep in mind the alterations in anatomy and physiology that occur during pregnancy.
- Stable pregnancies with a viable fetus should be monitored after trauma continuously for a minimum of 4 hours.
- Keeping the mother tilted 30 degrees to the left or in the left lateral decubitus position may alleviate hypotension and improve perfusion for the mother and fetus.
- Perimortem cesarean section should be performed only for a viable fetus with signs of life.
- Minimize the use of ionizing radiation to the pregnant patient, including CT and plain radiography, but imaging should not be withheld if it may provide significant diagnostic information.
- Nonionizing radiation, including ultrasound and MRI, is preferred for pregnant patients.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
PERSPECTIVE

Half of all deaths in children 1 to 14 years old are the result of trauma, and more than 15,000 traumatic deaths per year occur within this age group. More than half of these mortalities are directly related to motor vehicle collisions (MVCs). Injury accounts for approximately 30% of infant deaths as well. In the United States, estimates of mortality for children hospitalized after injury are uniformly low; however, most fatalities occur in the field before arrival at a health care facility, which contributes to an underestimation of the magnitude of overall mortality figures.

The most common single organ system injury associated with death in injured children is head trauma. Rates of 80% have been reported in patients with combined thoracoabdominal injuries. Because multiple injuries are common in children, the emergency physician must evaluate all organ systems in any injured child, regardless of the actual mechanism of injury.

Within the subset of MVCs, death rates increase steeply in adolescents (>13 years old). MVC mortality statistics show that the youngest occupant in the vehicle is the most vulnerable to injury. Among school-age children (5–9 years old), pedestrian injuries and bicycle crashes predominate. Falls from heights account for 25 to 30% of injury; submersion injuries account for 10 to 15%, and burns account for 5 to 10%. Throughout the United States, the number of children who are victims of violent acts has increased. Some children’s hospitals report that 25 to 35% of all pediatric trauma deaths are related to child abuse.

PRINCIPLES OF DISEASE

There are major anatomic and physiologic differences between pediatric and adult patients that play a significant role in the evaluation and management of a pediatric trauma patient (Box 35-1 and Table 35-1). Compared with adults, any given force is more widely distributed through the body of a child, making multiple injuries significantly more likely to occur in children. The proportionately large surface area of infants and children relative to weight predisposes them to greater amounts of heat loss as a result of evaporation. During resuscitation, even mild to moderate hypothermia has direct negative effects on cardiac function, inotropy, left-ventricular contractility, catecholamine responsiveness, platelet function, renal/hepatic drug clearance, and metabolic academia. Maintenance requirements for free water, trace metals, and minerals are therefore magnified compared to those for adults. Oxygen extraction and consumption, as well as glucose utilization, is much higher per kilogram in infants and small children than in adults. These factors contribute to a significantly higher energy and caloric requirement for an injured child compared with an injured adult. Finally, a child’s physiologic response to injury is different from an adult’s response, depending on the age and maturational state of the child and the severity of the injury. In contrast to adults, children have a great capacity to maintain blood pressure despite significant acute blood losses comprising 25 to 30% of total blood volume. However, changes in heart rate, blood pressure, and extremity perfusion may precede cardiorespiratory failure and should not be overlooked. Small children respond to decreased cardiac output primarily through an increase in heart rate, not contractility. Similarly, children have decreased pulmonary reserve and respond differently to stress than do adults. Children are primarily diaphragmatic breathers dependent on the excursion of the diaphragm to increase the volume of the thoracic cage, thereby increasing the volume of air exchanged per breath. Unlike adults, children’s elastic barrel-shaped chest wall prevents them from using their extra-thoracic muscles to lift the ribs in order to generate an increase in intrathoracic volume and, hence, increased tidal volume. When infants create greater negative pressures in their pleural spaces, their more elastic chest wall coves inward, leading to chest wall retractions.

CLINICAL FEATURES

Initial Assessment Priorities and Primary Survey

The highest priority in the approach to the injured child is ruling out the presence of life-threatening or limb-threatening injury. Treatment of these injuries must occur before proceeding with the rest of the physical examination. This initial assessment (the primary survey) and necessary initial resuscitation efforts must occur simultaneously. In general, the assessment and resuscitation should be addressed within the first 5 to 10 minutes of evaluation. Any infant or child with a potentially serious or unstable injury requires continual reassessment. Vital signs should be repeated every 5 minutes during the primary survey and every 15 minutes thereafter until the patient is considered stable. The primary survey for pediatric trauma patients can be remembered by A, B, C, D, E, and F.

Airway and Cervical Spine Stabilization

**Box 35-1** Anatomic Differences in Adults and Children: Implications for Pediatric Trauma Management

The child's body size allows for a greater distribution of traumatic injuries, so multiple trauma is common. The child's greater relative body surface area causes greater heat loss. The child's internal organs are more susceptible to injury based on more anterior placement of liver and spleen and less protective musculature and subcutaneous tissue mass. The child's kidney is less well protected and more mobile, making it susceptible to deceleration injury. Fifteen percent of pediatric patients presenting with hematura after trauma have underlying congenital abnormalities. Growth plates are not yet closed in pediatric patients, leading to Salter-type fractures with possible limb-length resultant abnormalities. The child's head-to-body ratio is greater, the brain is less myelinated, and cranial bones are thinner, resulting in more serious head injury.

The physician assesses for possible airway obstruction from injury, teeth, blood, constriction, or vomitus. The physician must know normal dental anatomy and development in order to better recognize the possibility of missing primary or secondary teeth. Efforts to perform cricoid pressure, or ligatures such as ties on gowns, can easily occlude the infant/child's airway with as little as 0.2 pounds of force. Excessive cricoid pressure is a preventable but common reason for difficulty passing the endotracheal tube once it has passed through the cords. Gurgling or stridor may indicate upper airway obstruction. While stabilizing the neck, the airway is opened with a jaw-thrust maneuver. Efforts should be directed toward clearing the oropharynx of debris. The clinician must consider the possibility of cervical cord injuries in all seriously traumatized children. Evaluation of the cervical spine in children is discussed later: A gentle, developmentally appropriate approach must be used if reliable information is to be gained. Any complaint of past or current neurologic deficit, neck pain, or significant trauma to the head, chest, abdomen, or other spinal level injury should raise concern for a cervical spine injury. Repeatedly asking a toddler, “Does this hurt?” will typically lead to a response of, “No, No, No, Yes” as the child tries to accommodate to what he or she believes the examiner must want for an answer. It is often more useful to watch facial expression and for other cues of discomfort. Table 35-2 describes priorities in the assessment of the pediatric airway.

</table>
The physician assesses for adequacy of chest rise; in a young child, this occurs in the lower chest and upper abdomen. Both the chest and the abdomen should move concordantly. Discordant motion is referred to as paradoxical breathing and is a sign of impending respiratory failure. The respiratory rate is also assessed. Rates that are too fast or too slow can indicate impending respiratory failure. Treatment is assisted ventilation. If ventilation is necessary, a bag-valve-mask device is recommended initially. Only the volume necessary to cause the chest to rise should be provided because excessive volume or rate of ventilation can increase the likelihood of gastric distension (increasing the risk of vomiting and aspiration) and impair ventilation further. Cricoid pressure may help decrease the amount of air entering the esophagus during positive-pressure ventilation. A nasogastric/orogastric (NG/OG) tube should be placed during the first few minutes of bag-valve-mask ventilation and should be considered in all seriously injured children. Gastric distention due to bag-valve-mask and air swallowing often leads to respiratory embarrassment and potential hypotension due to decreased venous return. In conscious children, placement of an NG or OG should be preceded by local anesthesia, using agents such as atomized or nebulized lidocaine plus lidocaine jelly. The overall amount of lidocaine given should be closely monitored to prevent accidental overdose.

Indications for endotracheal intubation of a pediatric trauma patient include (1) any inability to ventilate by bag-valve-mask methods or the need for prolonged control of the airway, (2) Glasgow Coma Scale (GCS) score of less than 9 to secure the airway and provide controlled hyperventilation as indicated, (3) respiratory failure from hypoxemia (e.g., flail chest and pulmonary contusions) or hypoventilation (e.g., injury to airway structures or spinal cord injury), and (4) the presence of decompensated shock resistant to initial fluid administration.

Compared with adults, intubation of pediatric patients involves special considerations (see Table 35-1).

In children younger than age 8 years, the cricoid ring is the narrowest portion of the airway. For this reason, the cricoid ring often forms a physiologic cuff on uncuffed endotracheal tubes. In general, uncuffed tubes are used in children younger than age 8 years; cuffed tubes may be indicated when more airway protection than that from an uncuffed tube is necessary or when high-pressure or more precise ventilatory management is necessary. In general, the orotracheal approach to intubation is recommended. Problems associated with nasotracheal intubation in children include impairment of tube passage by the acute angle of the posterior pharynx, the potential for causing or worsening bleeding within the oral cavity, sinusitis, and increasing intracranial pressure (ICP) with insertion.

There are many limiting factors that compromise ventilatory function in an injured child, including depressed sensorium, occlusion of the airway, painful restriction of lung expansion, and direct pulmonary injury. Determination of adequate ventilation is possible only in the face of airway patency and adequate air exchange. As noted previously, the diaphragm plays a special role in the maintenance of proper ventilatory status in children. It is easily fatigued in a young child and often is displaced by any process that promotes distention of the stomach. As such, it is advisable to consider early placement of an NG/OG tube to facilitate decompression of the stomach.

To assess “ventilation,” pulse oximetry is useful; however, pulse oximetry measures adequacy of oxygenation only. The measurement of exhaled CO₂ is useful to confirm endotracheal tube position. Historically, a colorimetric semiquantitative device was used to detect the presence of exhaled CO₂ in patients with perfusion. The use of continuous end-tidal CO₂ capnography provides far more information and continues to be underutilized. In addition to serving as an initial qualitative device to confirm successful intubation of the trachea, it may also provide an early warning of unintended extubation, tube kinking or partial occlusion, or ventilator malfunction. It also characterizes the response to therapeutic maneuvers instantaneously, provides a quantitative tool to manage the ventilatory aspects of respiration, and may provide prognostic information when used in patients with cardiac arrest. The lack of appropriate CO₂ production when the tube is in proper position often indicates poor perfusion. The use of end-tidal CO₂ capnography allows better ventilatory management during head injury resuscitation, and its values can be confirmed with a single venous or arterial blood gas. This can assist greatly with continuing ventilatory management without the need for recurrent blood draws and the inherent delays and discomfort of acquiring arterial blood gases. Table 35-3 describes priorities in the assessment of breathing in pediatric trauma patients.

C—Circulation and Hemorrhage Control

Shock is not defined by any specific blood pressure but is instead a state in which the body is unable to maintain adequate tissue perfusion. Maintenance of systolic blood pressure does not ensure that the patient is not in shock. The pediatric vasculature has the ability to constrict and increase systemic vascular resistance in an attempt to maintain perfusion. Signs of poor perfusion, such as cool distal extremities, decreases in peripheral versus central pulse quality, and delayed capillary refill time, are signs of pediatric shock, even when blood pressure is maintained at normal levels. Palpable pulses are detectable at a systolic blood pressure greater than 80 mm Hg in children over approximately 10 years of age; however, it may be felt at lower pressures in infants and children younger than 10 years of age. Pulses can frequently be felt at lower systolic blood pressures in infants. Normal capillary refill time is less than 2 seconds; however, many variables affect this clinical finding. Alteration in a child’s response to the environment or interaction with caregivers may indicate respiratory failure or shock. External hemorrhage should be sought and controlled with direct pressure. The assessment of circulation in pediatric trauma patients is described in Table 35-4.

be used. Preventing and treating hypothermia is not a matter of comfort for traumatized infants and children but, instead, one of survival (Table 35-7).

F—Family

In the management of children, the family could be added to the primary survey. Rapidly informing the family of what has happened and the evaluation that is proceeding helps lessen the stress of the caregivers. Allowing family members to be present during resuscitations is acceptable and often preferred by families. Some caregivers choose not to be present, but that choice should be given to them. If a caregiver is present, it is advisable to assign a staff member to be with him or her during the trauma resuscitation to explain the process.

Child life specialists and clergy are valuable members of the resuscitation team. They can not only serve the patient directly through their provision of comfort and developmentally appropriate explanations of medical activities but also serve as a single caring person for the child to focus on throughout their evaluation. They can also be instrumental in assisting the family to better understand what they may and may not do during and soon after the resuscitation. Families often wonder, but are afraid to ask, if they may touch the child, who can help with siblings, which siblings should be allowed to visit, what is the next step, and a myriad of other concerns. These special-

ists can assist in all these areas. They are also expert in “playing”—the art of distraction and visual imagery. They may also play a role as the quintessential patient advocate, ensuring that the health care providers focus on the patient and not only on the individual medical issue at hand. Child life specialists should be viewed as part of the resuscitation team.

### Secondary Survey

After completion of the primary survey and requisite procedures, the secondary survey is performed. The secondary survey is an organized complete assessment to detect additional injury not found on the primary survey. A more complete and detailed history is obtained at this time. Features of the history that need to be obtained can be remembered by the mnemonic **AMPLE** (Box 35-3). Ongoing assessment of the patient occurs after the secondary survey, and key points are summarized in Box 35-4.

### MANAGEMENT AND DIAGNOSTIC STRATEGIES

#### General Management Principles

All pediatric patients who have sustained major trauma should be placed on a cardiac monitor; receive supplemental oxygen; and have constant reassessment of vital signs, oximetry, and, when possible, end-tidal CO₂. Vascular access is best obtained by accessing the upper extremity for the establishment of two large-bore intravenous lines. In the absence of available upper extremity peripheral sites, lower extremity sites could be used. Many clinicians favor the femoral vein as a safe site for insertion of a central line by use of a guidewire technique. A guide
Ample history:

- Femoral line sizing estimates
  
  | 3 F | <3 kg |
  | 4 F | 3–10 kg |
  | 5 F | 10–20 kg |
  | 6 F | >20 kg |

- To be completed after the secondary survey
  - Complete head-to-toe examination
  - Appropriate tetanus immunization
  - Antibiotics as indicated
  - Continued monitoring of vital signs
  - Ensure urine output of 1 mL/kg/hr

Femoral line sizing estimates:

- To be expected after trauma and massive transfusion. When massive transfusion (>1 blood volume = approximately 80 mL/kg) is expected, most current guidelines appear to underutilize additional blood products. This leads to continued coagulopathy and likely contributes to unnecessary death and morbidity. Some experts now recommend, based predominantly on adult studies, that if massive transfusion is expected, blood and fresh frozen plasma (FFP) be given in a near 1:1 ratio, although other experts believe a ratio closer to 1:2.5 may suffice and decrease the risk of multiorgan failure. In general, FFP should be dosed at 15 to 25 mL/kg. Platelet transfusion dosing can be very confusing. Practically all platelet units currently used are apheresis packs from a single donor. Each apheresis unit roughly equates to six of the older concentrate units. The usual dose in trauma is 10 mL/kg; however, the response may be quite variable (i.e., it can vary by more than a factor of two) due partly to the heterogeneity of the concentration of platelets in an apheresis pack. A general goal in trauma patients is to raise the platelet count above 50 × 10^9/L. The platelet count should be rechecked at 1 and 24 hours after transfusion, more often if the patient has ongoing difficulties with hemostasis or need for recurrent transfusion of red blood cells. The primary goal of giving cryoprecipitate is to increase the fibrinogen to levels of 1 to 1.5 g/dL, especially after central nervous system trauma. Although dependent on the fibrinogen concentration in the individual cryoprecipitate bags, the dose is typically 0.1 to 0.2 bags/kg. Each bag of cryoprecipitate contains approximately 150 mg of fibrinogen and 80 units of factor VIII.

In contrast to adults, cardiogenic shock is a rare event in childhood injury. However, any degree of chest trauma associated with the presence of shock must alert the clinician to the possibility of concomitant myocardial contusion or rupture. Myocardial rupture should be apparent during the focused abdominal sonography in trauma (FAST) exam. The classic presentation of neurogenic shock due to loss of sympathetic tone and contractility involves hypotension with a relative bradycardia. Vasodilatation leading to a suboptimal systemic vascular resistance is the root cause of this hypotension. These patients are often hypothermic. Neurogenic shock typically occurs after injury to the sympathetic outflow tracks between T1 and L2. Generally, dopamine is the first-line agent for treatment of neurogenic shock. The mechanism and clinical findings of neurogenic shock are distinct from those of spinal shock. Spinal shock often presents with decreased systemic vascular resistance, a relative hypovolemia, and tachycardia. It is often treated with fluids and, when necessary, pressors with primarily alpha vasoconstrictive effects, such as phenylephrine.

Specifics of the head examination include pupillary size and reactivity, funduscopic examination, and palpation of the skull. Assessment of the cervical spine must be done carefully, with the patient in full cervical spine immobilization. As soon as feasible, the patient should be removed from the backboard with cervical spine immobilization maintained. Backboards are not only uncomfortable but also often rapidly cause necrosis at pressure points. There are no common indications to justify leaving children on backboards after their initial evaluation.

Assessment of the chest and internal structures involves inspection for wounds and flail segments, palpation for tenderness and crepitation, and auscultation for asymmetry, poorly transmitted breath sounds, or cardiac impulses. When airbags have deployed, occult trauma (e.g., ocular injury) should be expected and specifically ruled out. Similarly, a seat belt sign across the abdomen is a significant harbinger of serious traumatic injury.

Examination of the pediatric abdomen is most reliable when performed on a cooperative patient. It is an insensitive screen-

**Pain Control**

Pain control is an essential part of any trauma patient’s management. Pain control may include not only medications but also techniques designed to change the perception and attention of the patient away from noxious stimuli and toward more pleasant experiences. The mainstay of pain control is narcotic analgesics, which should be used appropriately. Fentanyl has an advantage over morphine due to its hemodynamic profile and should be used readily but appropriately. It does not cause the release of histamine with secondary hypotension. Initial orders should be for both a loading dose and a PRN dose so that the nurse can continue to adequately control and assess the patient’s pain after the physician has left the bedside.

In addition to narcotics for pain control, immobilization of fractures and extremities with significant soft tissue injury also helps control pain. Visual imagery and distraction techniques, as well as a consistent and calm approach to the patient, should be utilized. Child life specialists (when available), patient representatives, chaplaincy, and most parents can assist in this endeavor. When asked if they want pain medicine, many children will say “No,” even when they are in pain, because they are afraid of getting a shot or they interpret “pain medicine” as medicine that will cause pain. Basing pain medication on pain scales and common sense seems to be most appropriate.

In head-injured patients, fentanyl has the additional advantage of a short duration of action. If the patient has a mental status change, fentanyl clears quickly, making it possible to differentiate worsening brain injury from side effects of the medication. This is generally a better option than reversing the pain medicine and pain control with a narcotic antagonist. It is not humane to withhold pain medication completely in a traumatized patient whose mental status is of concern; it is better to titrate with smaller doses of short-lived medications. If immediate concern arises, the narcotic can be reversed with very small doses of naloxone.

**Diagnostic Evaluation**

**Laboratory Studies**

Blood sampling for a pediatric trauma patient is no different than that for an adult trauma patient; however, use of smaller blood collection tubes and microtechnique by laboratory staff may be necessary in infants and small children. All older pediatric trauma patients should be assessed for the possible use of drugs or alcohol as contributing factors to the traumatic event. In patients with hypovolemic shock, the hemoglobin alone is unreliable because equilibration will not have occurred at the time of presentation to the emergency department.

A bedside glucose should be obtained on all patients with significant trauma. Repeat testing 30 to 60 minutes after significant pediatric trauma may be indicated as well. Children’s glucose utilization and metabolic rate per kilogram is much greater than that of an adult, and they have far less substrate reserve in the form of glycogen stores. Any child with a change in mental status after trauma should have a bedside glucose
checked immediately. Any child requiring dextrose due to hypoglycemia will likely need an ongoing dextrose supply to prevent recurrence of hypoglycemia. In patients who can eat, this may be a meal with starches, fats, and protein. In others, it may require intravenous dextrose.

Radiology

The most important “traditional” radiographs to obtain on moderately to severely injured children are of the chest and pelvis to assess for sites of blood loss or potential causes of shock. In stable, alert children without distracting injuries, the pelvic film may be eliminated if no suggestion of sacral or pelvic fracture is found on thorough clinical exam. The following seven criteria are required to rule out any relevant pelvic fracture: patient age older than 3 years, no impairment of consciousness, no other major distracting injury, no complaint of pelvic pain, no signs of fracture on inspection, no pain on iliac or pubic symphysis compression, and no pain on hip rotation or flexion. In patients with remarkable sacral tenderness and negative plain films, a CT scan should be strongly considered. Sacral fractures can be difficult to discern reliably on plain films. The radiographs of the cervical spine may be delayed until after further diagnostic studies are obtained, depending on the clinical presentation of the patient.

Other radiographs are obtained based on the physical examination. For patients sustaining minor trauma, no radiographs may be needed. Children younger than 2 years with injuries consistent with child abuse should undergo a skeletal survey, including skull, chest, abdomen, and long bone radiographs. Generally, these should be completed on a nonemergent basis while in the hospital. In most cases, they can be scheduled in the inpatient radiology department with the pediatric radiologist or the most experienced radiologist on staff available to interpret the films.

Although not considered part of the primary survey, consideration of cervical spine CT instead of plain radiographs in those with mental status changes and significant trauma, those receiving a head CT scan for a head injury, and those at high clinical pretest likelihood for cervical fracture may be appropriate. Although the negative predictive value of plain radiographs in low-risk populations seems high, the sensitivity of plain films to detect fractures is far less impressive. The pretest likelihood of fracture must be considered when making decisions regarding the removal of cervical immobilization in children with apparently normal radiographs. Patients with continued neck pain despite negative radiographs and/or CT may require magnetic resonance imaging (MRI) evaluation, delayed flexion-extension views, or, in rare cases, evaluation by neurosurgery under fluoroscopy. The use of immediate flexion-extension views is rarely indicated or helpful.

Electrocardiogram after Electrical Injury

The majority of pediatric electrocution cases are due to household current (≤240 V). Asymptomatic patients who did not have ventricular tachydysrhythmias in the field or water contact at the time of their electrocution with household current and do not have dysrhythmias in the emergency department are at very low risk for significant arrhythmias. Current literature does not indicate a need for an electrocardiogram (ECG) or monitoring in these children. Those patients with normal and nonspecific ECG changes, when one is performed, remain at low risk. Nonspecific changes generally resolve within 24 hours. ECGs are indicated, as is cardiac monitoring for at least 4 hours, in patients who experience high-voltage electrocution.

SPECIFIC DISORDERS/INJURIES

Head Injury

Perspective

Head trauma is the leading cause of death among injured children and is responsible for 80% of all trauma deaths. Each year, 29,000 children younger than age 19 years experience permanent disability from traumatic brain injury. Falls account for 37% of pediatric head injuries, MVCs account for 18%, pedestrian injuries account for 17%, and falls from bicycles account for 10%. On an age-related basis, infants and toddlers are more prone to falls from their own height, school-age children are involved in sports injuries and MVCs, and all ages are subject to the sequelae of abuse.

Principles of Disease

An important anatomic difference of a pediatric patient compared with an adult is that the cranial vault of a child is larger and heavier in proportion to the total body mass. This anatomic characteristic predisposes children, specifically toddlers and infants, to high degrees of torque that are generated by any forces along the cervical spine axis. Sutures within the pediatric skull are both protective and detrimental to the outcome of head injury in these patients. Although the cranium may be more pliable relative to traumatic insult, forces are generated internally that predispose the pediatric patient to parenchymal injury in the absence of skull fractures. The pediatric brain is less myelinated, predisposing it to shearing forces and further injury.

Clinical Features

The clinician must obtain as many details regarding the traumatic event as possible. The height of the fall or injury is particularly important with regard to the development of associated injury. Most children fall from their own height. It is important to consider the quality of the surface at the point of impact, specifically the presence or absence of carpeting within the home or location of injury. Impact with an object increases the localized force even after a short fall and may lead to increased risk for fracture and intraparenchymal injury. Children involved in MVCs are best evaluated by the degree of restraint that was present during the time of the accident. An infant in a properly installed car seat is likely to have a better outcome than an unrestrained infant. Unrestrained children involved in high-speed crashes are prone to serious injury.

In most cases, it is important to establish whether there was alteration of consciousness at the time of the injury event. With playground trauma, the history may be vague, and the interpretation of any change in consciousness of the child may be regarded as an actual loss of consciousness. The behavior of the child after the event should include questions related to the presence or absence of irritability, lethargy, personality change, abnormal gait, or other alterations in behavior. Any worsening of these symptoms since the injury should also be reported.

The prognostic significance of vomiting after pediatric head trauma is unclear. There is no adequate study defining an acceptable time frame in which vomiting after head injury is benign in nature. The development of seizures after head trauma, in contrast to vomiting, has been well studied. A brief seizure that occurs immediately after the insult (with rapid return of normal level of consciousness) is commonly called an impact seizure. This seizure usually is not associated with intracranial parenchymal injury. A CT is not necessary if the only
concern is the impact seizure; the decision to scan should take into account the mechanism of injury and current neurological status of the child. An impact seizure does not mandate the institution of anticonvulsant therapy. Seizures that occur later (>20 minutes after the insult) portend the greater possibility of traumatic brain injury and the development of seizures at a later date. CT is indicated for children with late seizures after head injury. Patients who experience seizures later in the course of the posttraumatic event are best evaluated by the neurosurgical service. As in all instances of trauma, a careful history related to the possibility of substance abuse must be obtained.

The physical examination of a head-injured child must include strict attention to the ABCs of emergency care. Although internal injuries are important in the outcome of these patients, the maintenance of oxygenation and perfusion is paramount in eliminating further insult. Because the pediatric brain is sensitive to decreases in glucose, oxygen, and perfusion, their maintenance optimizes the chances of good recovery. Strict attention must be paid to the maintenance of euvolemia because cerebral perfusion pressure (CPP) is adequate only in the face of a normal mean arterial pressure (MAP). Conceptually, CPP is equal to MAP minus intracranial pressure (ICP): CPP = MAP – ICP. As the blood pressure is reduced, so is CPP. Localized cerebral perfusion pressure at the site of injury and in the areas surrounding it may vary greatly from that approximated by this formula. Pediatric patients with any form of head injury should be evaluated and protected from cervical spine injury.

Several methods are available for evaluating head-injured patients, including AVPU and the GCS. A commonly used modification of the GCS for children is shown in Table 35.6. Although widely utilized, none of the pediatric modifications of the GCS have been well verified. However, studies on the reliability of the GCS in predicting the outcome in children with traumatic brain injury provide optimism compared with those on head-injured adults. In a study involving 80 children with traumatic brain injury admitted to an intensive care unit (ICU), initial GCS scores were compared with eventual outcome.22 ICU length of stay and time to cognition relative (ICU), initial GCS scores were compared with eventual outcome.22 ICU length of stay and time to cognition relative to GCS scores indicated that scores greater than or equal to 6 were associated with favorable outcomes and neurologic status. Although the number of patients in this study was small, the important message is that no matter how the patient presents neurologically, all efforts should be initiated to ensure survival and maintain stable neurologic status in the emergency department.

Examining a brain-injured child involves mental status testing, cranial nerve testing, motor testing, sensory testing, and short-term memory testing, with additional cognitive function testing under stress when indicated. The evaluation of cranial nerve function is essentially no different from that of an adult. The most important aspect of motor and cranial nerve evaluation involves ruling out the presence of increased ICP. Common symptoms and signs of increased ICP in infants and children should be sought (Boxes 35-7 and 35-8).

Minor injury to the scalp of infants and children involves the development of three common injury complexes.24-27 In order to better understand these injury complexes, the layers of the “SCALP” (skin, connective tissue, aponeurosis, loose areolar tissue, and periosteum) must be considered. Caput succedaneum refers to injury with hematoma in the connective tissue layer. This is freely mobile and crosses suture lines. A subgaleal hematoma refers to a hematoma that is subgaleal within the loose areolar tissue above the periosteum. Lastly, cephalohematoma refers to a collection of blood under the periosteum. Since the periosteum is tightly adhered to the various suture lines, the cephalohematoma does not cross them. Bleeding from scalp wounds is often profuse and can lead to hypovolemic embarrassment in infants and small children if not quickly controlled. Although children may develop shock from a scalp injury, it is prudent to look elsewhere while controlling this bleeding.

Skull fractures in children occur in many different configurations.19,21,28 Linear fractures, the most common type of skull fracture, rarely require therapy and often are associated with good outcomes. Factors favoring a poor outcome include the presence of the fracture overlying a vascular channel, depression, a diastatic fracture, or a fracture that extends over the area of the middle meningeal artery. Diastatic fractures, or defects extending through suture lines, are different from linear fractures in that leptomeningeal cysts (growing fractures) may develop at these sites. Fractures of the basilar portions of the occipital, temporal, sphenoid, or ethmoid bones commonly occur in children. The presence of cerebrospinal fluid rhinorrhea and otorrhea has been associated with these injuries. Signs of basilar skull fractures in children are similar to signs in adults and include posterior auricular ecchymosis (Battle’s sign) and raccoon eyes (the presence of petechial subcutaneous hematoma).29

Strictly speaking, concussion is defined as a brain insult with transient impairment of consciousness. Amnesia is often involved. Patients who sustain concussive insults have anorexia, vomiting, or pallor soon after the insult. This transitional period is followed by rapid recovery to baseline. A CT scan is usually not indicated; if one is obtained, it is most often normal. In contrast, contusions are often the result of coup and contrecoup forces at work. Contusions may not be associated with
any loss of consciousness at the time of insult. Patients often present with associated symptoms, such as altered level of consciousness, severe headache, vomiting, or focal deficits on neurologic assessment. These injuries are clearly demonstrable on CT.

Traditional teaching regarding the development of epidural hematomas involves the typical triad of head injury followed by a lucid interval, followed by rapid deterioration as intracranial hemorrhage worsens. In contrast to epidural hematomas in adults, pediatric epidural hematomas may be the result of venous bleeding, which predisposes them to a delay in the development of symptoms. Guardians should always be informed of delayed signs and symptoms following head trauma that should prompt immediate reassessment. In any event, epidural hematomas are associated with a high incidence of overlying skull fractures (60–80% of cases). Patients with small fracture-related epidurals localized only to the site of the inner table fracture should be monitored closely in the hospital but often do not require surgical intervention.

Special attention should be directed toward infants and toddlers to rule out the presence of subdural hematomas. This clinical scenario is most often secondary to rupture of bridging veins and rarely is associated with the presence of overlying fractures (<30%). Subdural hematomas most commonly occur in patients younger than age 2 years, with 93% of cases involving children younger than age 1 year. Chronic subdural hematomas are most often encountered in patients who have been subjected to what has been termed the “shaken baby syndrome.” This clinical complex involves forcible shaking of the child with accelerating and decelerating forces impacting the cranial vault.30 This syndrome is most often due to child abuse; 22% of abused children have central nervous system injuries.

Patients present with nonspecific findings, such as vomiting, failure to thrive, change in level of consciousness, or seizures. Retinal hemorrhages are present in the majority of cases, and all patients should have careful funduscopic examinations to rule out the presence of these nearly pathognomonic findings. Definitive exams should be performed by an ophthalmologist after pupil dilation to characterize the specific type of retinal hemorrhage. Those that occur in multiple retinal layers, are diffuse, and extend to the periphery are more likely secondary to abuse. Similarly, in less severe evident trauma, subdural hematomas at multiple sites, over areas other than the convexities, in the posterior fossa, or in the posterior interhemispheric fissure should strongly suggest the possibility of nonaccidental trauma.31,32 Left to their own development, the worst cases may manifest with signs of increased ICP. Retinal hemorrhages are not observed in children with mild to moderate trauma from other causes and are not associated with a prior history of cardiopulmonary resuscitation; the presence of retinal hemorrhages suggests child abuse. Coagulation studies, platelet count, platelet function assays, and, when indicated, metabolic tests for glutaric aciduria should be performed in these cases as well.

### Diagnostic Strategies and Management

As a basic rule, serial examinations are the most reliable indicators of clinical deterioration.25,28 The presence of focality is a reliable indicator of a localized insult, whereas the absence of focality may be misleading. The signs of increased ICP usually develop late in the course of the process in infants. As in an adult, papilledema may require days to develop. The classic Cushing’s response (bradycardia and hypertension) is also unreliable in children. If ICP elevation is suspected, emergency intervention must be initiated immediately (Table 35-8).

The Monroe-Kelly doctrine describes the contents of the skull to be made up of essentially three compartments: brain, cerebrospinal fluid, and blood. The volume of the skull is fixed. Although not a perfect model, this doctrine suggests the effects that changes in each compartment may have on the others. For example, in the presence of an intracerebral hemorrhage of significant volume, either cerebral spinal fluid or brain must leave the cranial vault. Similarly, if the brain swells, cerebral spinal fluid, blood, or both must leave the cranial vault. When this balance is disrupted, and the autoregulatory system’s capacity to adapt is exceeded, the ICP rapidly increases. ICP can quickly reach a level that is not conducive to localized brain survival or continued blood flow to the brain. If left untreated, herniation may occur: An ICP over 20 to 25 mm Hg should be treated, but the absolute value less than this that should trigger treatment is unclear. From the standpoint of global cerebral perfusion, CPP is equated with MAP – ICP. However, this model does not allow the accurate prediction of CPP at the specific site of injury or within the ischemic penumbra. Measurement of oxygen extraction (using modifications of the Fick principle) and outcome studies have played a role in the following recommendations. In general, it is best to keep the cerebral perfusion pressure greater than 50 to 65 mm Hg in children and greater than 70 mm Hg in adults. There appears to be an age continuum with regard to necessary cerebral perfusion pressure. Hackbardt and coworkers demonstrated that the single greatest prognostic sign of outcome from traumatic brain injury in children was the ability to maintain a cerebral perfusion pressure greater than 50 mm Hg.33 Many have adopted this as the minimum acceptable cerebral perfusion pressure.

The use of anticonvulsants after moderate to severe head injury in children is controversial. Early prophylaxis does not decrease the incidence of late seizures and is not recommended for this purpose. Clearly, the effects on temperature, intracranial oxygenation, and cerebral perfusion during an early seizure after trauma are discordant with the management principles of acute brain injury. In addition, early seizures often disrupt the evaluation and management of the patient’s head and other trauma. However, the evidence for phenytoin effectiveness in preventing early seizures after trauma is weak at best. Also, Young and coauthors demonstrated that in moderate to severe head injury the incidence of early seizure was much lower than expected and that phenytoin did not substantially lower this risk.24 Others have suggested that topiramate or levetiracetam may be more effective with decreased risks of side effects.35,36 It may be prudent to treat seizures aggressively if they occur and to consider using sedative medications with anticonvulsant properties such as benzodiazepines while reserving the use of prophylactic phenytoin or fosphenytoin for the highest risk patients.

Most clinicians favor early and controlled intubation in pediatric patients with GCS scores that are deteriorating or are less than 9. However, in the out-of-hospital phase of care, or if the physician is not knowledgeable and experienced in pediatric rapid sequence induction, bag-valve-mask ventilation should be strongly considered during short transports and until additional, more experienced support personnel are available. An O2 tube should be placed if bag-valve-mask ventilation is utilized to decrease the chance of emesis and to prevent respiratory embarrassment from gastric distension with air. Isolated head injury is uncommon; a careful search for other injuries should be made using meticulous and repetitive examinations as well as indicated laboratory and imaging tests.

Herniation syndromes in children are similar to those in adults. Unilateral herniation is suggested early on by the presence of a unilaterally dilated pupil (compression of ipsilateral third

nerve parasympathetic fibers), contralateral hemiplegia (due to ipsilateral cerebral peduncle compression against the tentorium), and spontaneous hyperventilation. With progression, the ipsilateral eye may be noted to be looking downward and outward secondary to the loss of third nerve motor function but continued fourth and sixth cranial nerve function. Often, bilateral third nerve compression occurs very early, leading to bilateral “blown” pupils. In Kernohan’s phenomena, the temporal lobe compresses the contralateral cerebral peduncle against the tentorium, leading to ipsilateral paresis, making localization of the lesion challenging without neuroimaging. Small, sluggish pupils, decorticate posturing, and Cheyne-Stokes respirations characterize early central diencephalic herniation. If this progresses and extends to the pons or medulla, small, sluggish pupils, decorticate posturing, and Cheyne-Stokes respirations characterize early central diencephalic herniation. If this progresses and extends to the pons or medulla, the patient will present with fixed and dilated pupils, flaccid muscle tone, and slow or apneustic breathing or frank apnea and cardiorespiratory arrest. Management of suspected acute herniation begins with immediate controlled hyperventilation. Clinical endpoints of hyperventilation are improved patient status or constriction of dilated pupils. End-tidal CO₂ capnography is used with arterial or venous blood gas correlation to assess adequacy of hyperventilation with a target partial pressure of carbon dioxide (PaCO₂) of 30 to 35 mm Hg. Excessive hyperventilation can result in excessive cerebral vasoconstriction and secondary brain injury; ventilation is started at an age-appropriate rate, and then the rate is increased until pupillary function returns. Subsequent management of herniation includes hyperosmolar agents acutely, followed by other specific interventions in the ICU.

**Radiology**

**Skull Radiographs.** Most clinicians agree that firm indications for skull radiographs alone include the skeletal survey involved with the evaluation of child abuse, establishment of a functioning ventricular peritoneal shunt, some penetrating wounds of the scalp, or the suspicion of foreign bodies underlying scalp lacerations. In children requiring neuroimaging due to concern for intracranial injury, plain skull radiography lacks sufficient sensitivity to be used as a screening tool and a noncontrast CT scan is the recommended test.

**Computed Tomography of the Head.** There has been a considerable amount of research on the indications and relative value of CT scanning in pediatric head-injured patients. A large study evaluated 185 children ages 2 to 17 years with loss of consciousness and GCS scores of 15 after mild head injury. The children were grouped according to physical examination findings, neurologic status, and whether the head injury was isolated or nonisolated. Patients with obvious skull fractures were excluded. Two variables were highly associated with the presence of intracranial hemorrhage: the presenting neurologic status and the presence of multiple injuries. None of the 49
neurologically normal children with isolated head injury had intracranial hemorrhages. All patients with intracranial hemorrhages were noted to have other traumatic insults on physical examination. The authors concluded that after isolated head injury with any loss of consciousness, children older than 2 years of age who were neurologically normal could be discharged without a CT scan after careful physical examination alone.

Other studies contradict these findings, establishing a clear association with parenchymal injury and loss of consciousness. Currently, recommendations for CT scanning include the presence of neurologic deficits, GCS scores of less than 14, and injury patterns that are the result of major forcible insults. Studies have shown various combinations of characteristics that make significant intracranial injury very unlikely but have provided less guidance in selection of which patients actually need a head CT (high negative predictive value but low positive predictive value). Studies have shown that if these rules are utilized, they must be used exactly as they were performed in the study to be effective. Dunning and coauthors’ meta-analysis showed a statistically significant correlation of intracranial hemorrhage with focality (relative risk \( RR = 9.4 \)), skull fracture (\( RR = 6.1 \)), altered level of consciousness (\( RR = 2.23 \)), and GCS scores greater than 15 (\( RR = 5.51 \)). Children younger than 1 year of age are a special challenge to the clinician because their neurologic milestones are more difficult to evaluate. Within this age group, any loss of consciousness, protracted vomiting, irritability, poor feeding, or suspicion of abuse should trigger strong consideration for CT scanning. The value of brief loss of consciousness and the determination of the need for CT in the child more than 1 year old are less clear, but loss of consciousness lasting longer than a minute is considered an indication for neuroimaging by many practitioners.

The evaluation of infants with minor closed-head injury was studied in a series of 668 infants younger than 2 years of age who underwent CT scanning, in which a subset of 92 infants younger than 2 months of age was further scrutinized. The presence of a significant scalp hematoma highly correlated with underlying parenchymal brain injury. The authors recommended CT scans for these patients.35

## Cervical Spine Injury

### Perspective

In the United States, more than 1100 children sustain spinal injury annually. Cervical injury patterns vary with the age of the patient. Fractures below the C3 level account for only 30% of spinal lesions in children younger than 8 years of age, which differs dramatically from the patterns seen in adults. Likewise, spinal cord injury (SCI) without radiographic abnormality (SCIWORA) has been found in 25 to 50% of spinal cord injuries in this same age group. SCIWORA may be a misnomer in the era of MRI. Intra- or extraneural findings are usually seen immediately on MRI but may be delayed, necessitating immobilization and a follow-up MRI to prevent late or recurrent injury. Length of immobilization is controversial, but it may be up to 12 weeks.

### Principles of Disease

Anatomic features of the cervical spine approach adult patterns between the ages of 8 and 10 years (Box 35-9). Injury patterns identical to those of adults are often not fully manifested, however, until age 15 years. The pediatric spine has greater elasticity of the supporting ligamentous structures than the adult spine. The joint capsules of the child have greater elastic properties, and the cartilaginous structures are less calcified than in adults. In the spine, there is a relatively more horizontal orientation of the facet joints and uncinate processes, and the anterior surfaces of the vertebral bodies have a more wedge-shaped appearance. Compared to the adult, the child has relatively underdeveloped neck musculature and a head that is disproportionately large and heavy compared with the body. Both of these differences lead to an “anatomic fulcrum of the spine” in children that is at the level of the C2 and C3 vertebrae versus the lower cervical vertebrae as found in adults.

### Clinical Features

Any patient with severe multiple injuries should be considered to have an SCI until proved otherwise. Likewise, significant head, neck, or back trauma and trauma associated with speed, MVCs, and falls from any height (especially those with associated head injury) should raise suspicions for SCI and be evaluated appropriately. The evaluation of a pediatric patient should begin with a primary survey to assess airway patency, ventilatory status, and perfusion. After initial evaluation and stabilization, the cervical region can be examined. Palpation...
of the neck for pain and bony deformity should be performed. If the patient has pain or tenderness, closely watching his or her facial expression will generally indicate more than asking, “Do you have pain?” Any continued concern or perceived discomfort should be taken seriously because ligamentous discomfort is sometimes subtle. In academic institutions, it is common for three or four people to repeat each aspect of the exam. It is not uncommon for children who originally tell you that something hurts to tell new examiners that it does not hurt because they quickly learn that when they affirm that they have pain, stimulus will continue to be applied, making the pain worse. One examiner finding tenderness should be enough to consider further evaluation.

Some factors, such as tenderness or pain with palpation, may be underappreciated in a child who is not yet old enough to talk. Similarly, patients with head injury, decreased level of consciousness, or distracting injury or those who are intoxicated may not reliably localize pain in the cervical region, and spinal precautions should be maintained to avoid potential additional injury.

The neurologic examination in a pediatric patient can be difficult, but several factors should be evaluated in a patient with suspected cervical spine injury. Pain in the cervical region should raise suspicion of cervical spine injury. Likewise, paralysis, perceived paresthesias, ptosis, and priapism are neurologic signs highly correlated with SCIs. Complaints of paralysis or paresthesias, even if completely resolved at the time of examination, should be considered an indication of SCI until proven otherwise. Finally, upper extremity position and function can help elucidate the presence and level of an SCI.

Several characteristic SCI syndromes can be diagnosed on initial emergency department evaluation. Spinal cord injuries are generally described as either complete or incomplete depending on the presence or absence of sensory or motor function. Incomplete SCI has a better prognosis for recovery of some motor function after spinal shock resolves. Incomplete lesions have some preservation, even if slight, of sensory or motor function below the area of SCI and at the area of sacral nerve distribution. The determination of complete or incomplete is not a one-time assessment and cannot be reliably made until after spinal shock has resolved. The performance of a rectal exam (or anal wink testing) or bulbocavernous reflex testing in males can assess for sensation and motor ability in the sacral distribution. Central cord syndrome (seen mostly in extension injuries to the cervical spine) typically consists of arm findings (e.g., decreased tone) greater than leg findings and distal symptoms greater than proximal symptoms (e.g., burning pain in the fingers and hands). Anterior cord syndrome (associated with flexion injuries to the cervical spine) is characterized by complete motor paralysis with loss of pain and temperature sensation; however, position and vibration sensation are preserved in this disorder. Finally, Brown-Séquard syndrome represents hemisection of the spinal cord with ipsilateral loss of motor function and proprioception. There is also contralateral loss of pain and temperature sensation. SCI syndromes are rare in children.

Radiology

Some experts believe that children with neck pain, involvement in an MVC, or any suspicion of cervical injury should receive radiographic evaluation because when used as a screening tool, these factors may be very sensitive in identifying cervical spine injuries in this patient group. Other experts support the use of the NEXUS criteria to determine who needs cervical radiographs. These criteria were derived from a study of 3065 children younger than age 18 years; however, only 4 of 30 cervical spine fractures were in children younger than age 9 years, and none of the 88 children younger than age 2 years had cervical fractures.47,48 No pediatric cases of SCIWORA were found and the data showed that 45.9% of cervical spine injuries in their cohort were between the levels of C5 and C7. This may reflect the fact that 2160 of the pediatric patients were between 8 and 17 years old. The sensitivity for detection of cervical fractures was reported as 100% (95% confidence interval = 87.8–100%); however, less than 1% of children in the study had an injury, making the 100% negative predictive value less meaningful and the sensitivity (at least in young infants) suspect.47 The majority of injured patients were older than age 9 years and had characteristics more similar to adults than infants.48 Because of the limitations of the NEXUS criteria as they pertain to children, a low threshold for imaging must be maintained in children with mechanisms worrisome for cervical injury. A report of discomfort, any significant distracting injury, or even transient neurologic symptoms should be considered an indication for radiologic evaluation.

Radiographic evaluation routinely should consist of three views: a cross-table lateral view, an anteroposterior view, and an open-mouth odontoid view to help visualize the odontoid process of C1. The sensitivity of the three-view cervical spine series is highly variable. The pretest likelihood of fracture must be taken into account when acting on the result or choosing an imaging modality. Interpretation of plain cervical spine radiographs in children may be especially challenging because of the anatomic changes that occur with growth (see Box 35-9). In addition, pseudosubluxation of C2 on C3 is common in children up to adolescence, occurring in approximately 40% of patients.49 The emergency physician distinguishes between pseudosubluxation and true subluxation by the posterior cervical line and the relationship of the spinolaminar line, also called the line of Swischuk, to the anterior cortical margin of the spinous process at C2. A line is drawn from the anterior cortical margin of the spinous process of C1 down through the anterior cortical margin of C3. If this line at C2 crosses the anterior cortical margin of the spinous process at C2 or is anterior to it by less than 2 mm and no fractures are visualized, the patient likely has pseudosubluxation versus true subluxation at that level (Fig. 35-1).

An important criterion for radiographic clearing of the cervical spine is complete visualization of all seven cervical vertebral bodies down to and including the C7-T1 interface. The predental space should not exceed 4 or 5 mm in children younger than 10 years of age, and the prevertebral soft tissue space should not be greater than normal (variable but generally <1/3 to 1/2 vertebral body width). The four cervical radiographic lines should be evaluated, and the atlanto-occipital alignment should be assessed for dislocation in this region. Other imaging modalities that can be used to delineate cervical fractures include thin-section CT and magnetic resonance imaging. If the dens cannot be adequately assessed by the open-mouth odontoid view, then a transforaminal view or CT scan should be utilized. Patients with high clinical suspicion for fracture but negative plain radiographs should be considered candidates for computed tomographic evaluation and radiologic, orthopedic, or neurosurgical consultation. Eubanks and co-workers provide a discussion on clearing the pediatric cervical spine in their review article.50

Classically, young children have been considered at greater risk for upper cervical spine injury. Unfortunately, many occipital cervical junction injuries are immediately fatal. However, survival is possible in some cases.51 Early detection and immobilization is crucial. Occipital cervical junction injuries should be suspected in any child pedestrian versus vehicle
accident, especially if a child presents with a laceration under the chin from a forward fall. In many fatal cases, distraction and displacement is obvious. However, in nonfatal cases it can be subtle. A Power’s ratio greater than 1 indicates an atlanto-occipital dislocation until proven otherwise (normal, approximately 0.77). Power’s ratio is calculated as the ratio of the distance from the basion to the posterior cortex of the atlas divided by the distance from the opisthion to the posterior cortex of the anterior arch of the atlas. An additional method to suggest this injury is to draw a vertical line from the posterior border of the odontoid and then measure the distance from this line to the basion. If this distance is greater than 12 mm, then atlanto-occipital separation should be suspected. In addition, a traumatic or even sometimes non-traumatic atlantoaxial rotatory subluxation should be suspected in a child with a fixed rotatory cervical abnormality. Classically, this can be differentiated from a muscular torticollis in non-traumatic cases by the history, the time course, and palpation of the sternocleidomastoid muscle on the side contralateral to the direction in which the chin is pointing. When atlantoaxial rotatory subluxation cannot be confidently ruled out clinically, plain radiographs or CT scan should be utilized. In children with upper cervical spine tenderness, it is prudent to consider a fracture of the synchondrosis between the odontoid and C2. This can be difficult to diagnose on plain radiograph, but it is often recognized as a subtle anterior tilt to the odontoid on C2. A CT scan with sagittal reconstructions will clarify this entity.52

Management

There are two phases of SCI. Direct injury (initial phase) results in largely irreversible injury to the spinal cord. Indirect injury results from preventable or reversible injury to the spinal cord secondary to ischemia, hypoxemia, and tissue toxicity. Resuscitation of a patient with injury to the cervical spine should focus on prevention or minimization of the indirect causes of injury to the cervical spine. Management of possible spinal cord or column injury should begin in the out-of-hospital phase of emergency care. Most injured children arrive at the emergency department with adequate immobilization. Some more recent evaluations of traditional cervical collars and rigid backboards have shown less than adequate neutral positioning of pediatric patients related to their relatively large cranium in proportion to the rest of their body. Nevertheless, in the absence of modified backboards with cutouts for the occiput of the child, the child should be immobilized with stiff cervical collar, rigid backboard, and external fixation by means of head blocks, cloth tape, or straps to provide adequate precautions. Appropriate padding should be placed under the patient to approximate neutral alignment of the cervical spine and help prevent pressure-related injury. Some emergency medical service agencies’ protocols call for small children to be immobilized in their car seats in some circumstances.

Breathing should be assessed to determine the presence of hypoventilation. Patients with SCI may hypoventilate because of diminished diaphragmatic activity or intercostal muscle paralysis. Otherwise normal children held in a supine position have shown reduced ventilatory abilities as measured by the forced vital capacity. Head or chest injury or pulmonary compromise related to contusion, aspiration, or other causes likewise may contribute to ventilatory embarrassment. Supplemental oxygen should be given routinely, and ventilatory assistance by bag-valve-mask ventilation or definitive airway management should be considered in the presence of clinically significant hypoventilation. Finally, circulatory status must be assessed early in the trauma patient and needs to be addressed promptly to prevent end-organ perfusion deficits. Hypotension can result from hypovolemia, neurogenic shock, spinal shock, or a myriad of other less common causes. Spinal shock presents with lower extremity findings of SCI, with flaccid paralysis of skeletal and smooth muscle leading to the appearance of a relative hypovolemia due to diminished systemic vascular resistance. Spinal shock generally resolves in hours to approximately 1 day once some spinal level reflexes return below the site of injury. Neurogenic shock typically occurs after injury to the spinal cord above the level of approximately T6. Patients with neurogenic shock lose their sympathetic tone and present with hypotension in the face of unopposed parasympathetic action such as bradycardia. In each case, fluid administration, parasympathetic receptor blocking agents such as atropine or glycopyrrolate, and vasopressors with chronotropic, vasoactive, and inotropic characteristics (e.g., dopamine) are used. If spinal shock with normal chronotropy and inotropy is found, then fluids and agents with more peripheral vascular vasoconstrictive properties may be preferable, such as phenylephrine or norepinephrine. Spinal shock remains a diagnosis of exclusion, once hemorrhagic shock has been definitively eliminated.

Figure 35-1. Spinolaminar line. Use only to access anterior displacement of C2 on C3. A line is drawn from the cortex of the spinous process of C1 to the cortex of the spinous process of C3, and the relationship of the spinous process of C2 is noted. A, Normal line passing through the cortex of C2. B, Normal line passing within 1.5 mm of the cortex of C2. C, Abnormal line passing greater than 2 mm anterior to the cortex of C2, suggesting underlying fracture of posterior elements of C2. (From American College of Emergency Physicians, American Academy of Pediatrics: APLS: The Pediatric Emergency Medicine Resource, 4th edition, Dallas, Elk Grove Village, Ill, 2004, the College and the Academy.)
Any patient with definite SCI requires added precautions to ensure appropriate immobilization of the cervical spine. The use of intravenous steroids for blunt injury to the spinal cord continues to be debated in the literature (see Table 35-8). Immediate evaluation by a spinal cord specialist should be sought for all children with SCI. In the absence of such a specialist, the patient should be transported to a center with adequate facilities to care for spinal cord-injured patients. Even when thoracic or lumbar fractures exist, patients should be expeditiously removed from the backboard to prevent discomfort and morbidity. Sliding boards (smooth movers) can be used to move patients onto scanner tables and back to their trauma beds. Mandatory interhospital transfer rules that require patients to remain on backboards during transport should be discouraged. The initial physician receiving the patient should be able to determine the necessity of the backboard for cervical spine immobilization during transport and, when appropriate, remove the patient from the board before transport.

Cardiothoracic Injury

Perspective

Most serious chest injuries in children (83%) are the result of blunt trauma.6,53 Most result from MVCs. Isolated chest injury is a relatively infrequent occurrence considering the typical mechanisms of blunt trauma in the pediatric patient. The presence of significant chest injury increases the potential for multisystem trauma mortality by a factor of 10. Sequelae of blunt injury include rib fractures and pulmonary contusion (50%), pneumothorax (20%), and hemothorax (10%).

The overall mortality of pediatric chest trauma is nearly equivalent for blunt versus penetrating trauma. Children subjected to penetrating trauma, in contrast to the injuries associated with blunt trauma, often die from the primary insult. Penetrating trauma accounts for only 15% of thoracic insults in children. Nationwide misuse of firearms has resulted in an increasing incidence of penetrating trauma, often with children as victims. The vast majority of these cases are related to the criminal use of handguns; however, improper storage and poor parental supervision lead to devastating consequences in a relatively small, but nevertheless preventable, number of cases each year. Families of children with emotional difficulties or depression should consider removing guns from their homes due to their lethality when used as an instrument of suicide. Specific clinical patterns should alert the clinician to the potential for concurrent abdominal and thoracic injury. Any patient with penetrating trauma at or below the level of the nipples falls into this category. Apparent isolated thoracic trauma does not exclude abdominal injury. All patients with self-inflicted penetrating trauma should also be assessed for ingested toxins.

Principles of Disease

It is important to understand the physiology of pediatric respiration when considering the potential for early decompensation following chest injury. Infants and young children are preferential diaphragm breathers, and any impairment of diaphragmatic mobility compromises ventilation. The presence of gastric distention elevates the diaphragm and severely diminishes the vital capacity of a child. In addition, the particular types of muscle fibers involved in the diaphragm of infants and young children predispose to the sudden development of apnea when these muscles become fatigued. Unlike adults, whose thoracic wall musculature can pull the ribs up anteriorly giving a larger circumference to the chest wall, children’s chest wall circumference does not change drastically during respiration because their chest is barrel-like throughout the respiratory cycle. This also decreases the ability of children to increase their vital capacity. For these reasons, children will increase ventilation typically by increasing their respiratory rate. Most important, the presence of adequate oxygenation in a pediatric patient does not always ensure sufficiency of ventilation; confirmatory auscultatory and other physical findings are essential. End-tidal CO₂ capnography can be very useful in this regard in both the intubated and the nonintubated trauma patient.

Infants and children are anatomically protected against blunt thoracic cage trauma because of the compliance of the rib cage. Compressibility of the rib cage dissipates the force of impact, which lessens the likelihood of bony injury. These protective mechanisms also may mask fairly complex pediatric thoracic insults. The compliance of the rib cage allows significant injury to occur with little apparent external signs of trauma. Multiple rib fractures are a marker of serious injury in children, with child abuse being the most likely etiology, especially when fractures are posterior and in various stages of healing. In addition, the pediatric mediastinum is mobile, which favors the development of rapid ventilatory and circulatory collapse in the presence of a tension pneumothorax.

Specific Disorders

Pneumothorax. The development of a traumatic pneumothorax is commonly associated with significant pulmonary injury. In contrast to spontaneous pneumothoraces, these insults do not resolve spontaneously and often are associated with the presence of a hemothorax. Signs and symptoms include external evidence of chest trauma, such as abrasion, contusion, or ecchymoses; tachypnea; respiratory distress; hypoxemia; and chest pain. Decreased breath sounds may not be appreciated in children with pneumothoraces because of the wide transmission of breath sounds in the chest and upper abdomen. It is critical to listen to the chest from the axilla in children. This location helps with lateralization to distinguish decreased breath sounds on one side compared to the other and, after intubation, to assess for proper endotracheal tube position.

Management of a hemopneumothorax noted on chest radiograph includes the placement of a large-caliber chest tube placed far enough posteriorly, near the mid-axillary line, to prevent encroaching on more anterior soft tissue that will later become part of the breast. Chest tube size for hemopneumothorax management can be estimated as four times the size of the endotracheal tube that would be used in the patient (the age plus 12–16) or can be found on a length-based resuscitation tape. A chest tube should be considered for any patient with a pneumothorax who will be undergoing mechanical ventilation. In the most conservative of scenarios, such as small (<20%) simple pneumothoraces that are not under tension in a child who will not be mechanically ventilated, the child may be observed carefully for extended periods with 100% oxygen supplementation for nitrogen washout, and reassessment can be done by repeat chest radiographs at selected intervals or a pigtail catheter can be placed percutaneously using a modified Seldinger technique.

Open Pneumothorax. An open pneumothorax exists when the chest wall is injured sufficiently to allow bidirectional flow of air through the wound. The patient is unable to expand the lung because of equalization of pressures between the atmosphere and the chest cavity. Ventilation and oxygenation are severely impaired.
Management of an open pneumothorax is dictated by the size of the defect and the amount of respiratory compromise. Simple, small puncture wounds in a breathing patient may be treated by covering the chest wall defect with occlusive dressing, such as sterile petroleum gauze. A separate incision should be made for the placement of a thoracostomy tube. As in all cases, defects that are too large to seal adequately or patients who are severely impaired with regard to ventilation are candidates for intubation.

**Tension Pneumothorax.** Pulmonary air leaks that occur in a one-way valve arrangement favor the development of a tension pneumothorax. Increasing amounts of free air within the pleural cavity cause the mediastinal structures to shift toward the opposite side, compromising cardiac output. The final common pathway involves hypoxia, hypotension, and refractive shock. Most patients with tension pneumothoraces present with severe respiratory distress, decreased breath sounds (often bilaterally), and a shift in the point of maximal cardiac impulse. In the worst scenario, the shifted mediastinum forces contralateral tracheal deviation and distention of the neck veins due to decreased venous return to the thorax. In pediatric patients, signs of tension pneumothorax are often subtle. A short neck and increased soft tissue may make detection of tracheal deviation difficult. Pediatric patients with tension pneumothorax may only have subtle signs or present with only tachycardia, shock, and respiratory distress. The emergency physician should consider the diagnosis of tension pneumothorax and, if detected or strongly suspected, should treat the patient immediately with decompensation. Without adequate decompression, respiratory embarrassment, hypotension, and circulatory collapse will occur.

In the out-of-hospital setting, treatment includes needle thoracostomy placed in the second intercostal space in the midclavicular line or possibly in the fourth intercostal space just above the rib and anterior to the mid-axillary line. The needle should be placed above the rib margin to avoid injuring the intercostal vessels. In the emergency department, definitive treatment involves the use of a large-caliber thoracostomy tube that favors drainage of the tension pneumothorax and any accompanying hemothorax.

**Hemothorax.** Significant bleeding may occur when injury is directed toward the intercostal vessels, internal mammary vessels, or lung parenchyma. Without an upright chest film, it is difficult to quantify the degree of bleeding on plain radiographs. A slightly less radiolucent appearance on the affected side of the chest may be the only sign on a supine radiograph, often associated with a pneumothorax. Development of a massive hemothorax is rare in children and is associated most often with severe impact, such as that seen in high-velocity MVCs, falls from extreme heights, or the use of high-powered firearms. These injuries must be evaluated and treated quickly. Clinically, patients present with decreased breath sounds and dullness to percussion on the affected side. A pneumothorax may coexist with a hemothorax. The pediatric patient may present with early or late signs of hypovolemic shock.

Any alteration in cardiovascular sufficiency should be treated with rapid fluid replacement with isotonic crystalloid solutions. The clinician must also prepare for transfusion with the institution of red blood cell replacement as necessary. Patients who present with profound shock may receive either type-specific or O-negative blood; crossmatched blood may be used for more stable patients. The amount of blood that is salvaged from the chest tube should be quantified to help determine the need for red blood cell replacement. Many centers have the capability to salvage blood from hemothoraces and reinfuse using an autotransfuser. As in all cases of trauma, initial measurement of the hemoglobin is often unreliable and typically underestimates the amount of blood loss due to inadequate time for equilibration.

The treatment of hemothorax includes a tube thoracostomy. The tube needs to be large enough to occupy most of the intercostal space and should be placed laterally and directed posteriorly. In the supine patient with simple pneumothorax, chest tubes are directed superiorly; in hemopneumothorax, they are directed postero-medially. As in all interventions, repeat chest radiographs should be obtained to confirm tube position and document improvement in lung expansion. The emergency physician is often able to stabilize the patient with red blood cell replacement until surgical intervention is achieved.

Indications for thoracotomy include evacuated blood volumes exceeding 10 to 15 mL/kg of blood immediately after the placement of the chest tube, persistent blood loss (e.g., exceeding 2–4 mL/kg/hr over 3 hours), or continued air leak. Emergency department thoracotomy is reserved for patients with penetrating trauma who deteriorate to cardiopulmonary failure despite maximal resuscitation in the out-of-hospital setting or emergency department. Guidelines for emergency pediatric thoracotomy are often institution specific. Cothren and Moore have suggested an algorithm to guide emergency department thoracotomy in multiply injured trauma patients. Contraindications for emergency department resuscitative thoracotomy after out-of-hospital cardiopulmonary resuscitation (CPR) include (1) blunt trauma with CPR for greater than 5 minutes with asystole and no signs of life on presentation without ultrasound evidence of cardiac tamponade and (2) penetrating trauma with CPR for greater than 15 minutes and asystole with no signs of life on arrival without ultrasound evidence of cardiac tamponade. Patients with penetrating chest trauma and CPR for less than 5 minutes may warrant a left anterior thoracotomy, whereas patients with blunt trauma should have rapid assessment by ultrasound for tamponade. If tamponade is present and CPR has been performed for less than 15 minutes, then a left anterior thoracotomy may be indicated.

**Pulmonary Contusion.** Penetrating and blunt thoracic trauma may result in the development of a pulmonary contusion. The compliance of the rib cage in children renders them susceptible to the development of pulmonary contusion even in the absence of external signs of chest trauma. Injury to capillary membranes allows the collection of blood within the interstitial spaces, resulting in hypoxia and respiratory distress. If bleeding is severe enough, oxygenation and ventilation are impaired. Initial chest radiographs may not show the classic findings of pulmonary consolidation. In addition, in the early stages of injury, blood gases may be normal.

Treatment of pulmonary contusions includes a careful evaluation for the presence of additional injuries because significant force is necessary to cause the contusions. Most patients may be treated with supplemental oxygen and close monitoring. Most pulmonary contusions resolve without sequelae. Rare cases are associated with the development of acute respiratory distress syndrome.

**Traumatic Diaphragmatic Hernia.** Children involved in MVCs who are wearing lap belts are predisposed to the development of diaphragmatic herniation. Mechanisms of injury involve sudden increases in intra-abdominal pressure. Patients initially present in stable condition, with the degree of respiratory distress directly proportional to the amount of abdominal contents that protrude into the pulmonary space. The presence of bruising from lap belt–only compression should alert the clinician to the possibility of diaphragmatic hernia and other intra-abdominal injuries (small bowel injury) and the possibility of associated thoracolumbar spinal insults such as Chance
fractures. Most commonly, the herniation occurs on the left side because the liver is protective against diaphragmatic rupture on the right.

Initial management for these patients involves placement of an NG tube to decompress the stomach. In cases of severe respiratory distress, intubation is indicated. Bag-valve-mask ventilation is avoided whenever possible. Surgery is required for repair of the injury.

Cardiac and Vascular Injuries. Injuries to the heart and large vessels are uncommon in children. The most common traumatic cardiovascular injury sustained by children is myocardial contusion. Patients often present with chest wall tenderness or may have a complaint of generalized chest pain. Tachycardia is the most common finding. Elevation of myocardial enzymes may be diagnostic. Patients with myocardial contusions should be monitored closely for the development of dysrhythmias and impaired myocardial function; however, in most cases of myocardial contusion, there are no long-term sequelae. The most life-threatening scenario involving the cardiac structures is the development of cardiac tamponade. Penetrating wounds to the chest are not rare but are potentially survivable if myocardial penetration and tamponade are recognized immediately. Extravasated blood fills the pericardial space and impairs cardiac filling during diastole. Tamponade is most often the result of a penetrating wound. Firearm insult often causes sudden death, and blunt trauma rarely results in the development of cardiac tamponade. Clinically, patients present with tachycardia, distant heart sounds, narrow pulse pressure, jugular venous distension, and pulsus paradoxus. In the scenario of profound hypovolemia, venous distention is absent. The final common pathway involves the development of pulseless electrical activity. Ultrasound can characterize this injury in seconds and guide therapy.

In cardiac and vascular injuries, the electrocardiogram may show anything from tachycardia with low voltage (pericardial tamponade) to findings consistent with acute myocardial injury (ST segment elevation). In the subacute scenario, echocardiography often makes the diagnosis. Bedside transthoracic echocardiography defines the degree of pericardial effusion present and the significance of any diastolic dysfunction present. A simple single subxyphoid view provides the emergency physician with an excellent view of the pericardial sac and heart. Pericardiocentesis may be diagnostic and therapeutic. Definitive treatment involves drainage of the fluid from the pericardial sac. In certain situations, the amount of pericardial blood and clot necessitates the performance of a thoracotomy to evacuate the pericardium adequately.

Commotio Cordis. Commotio cordis is a disorder described in pediatric patients that results from sudden impact to the anterior chest wall (e.g., as seen in baseball injuries), which causes cessation of normal cardiac function. The patient may have an immediate dysrhythmia or ventricular fibrillation that is refractory to resuscitation efforts. Significant morbidity and mortality are associated with this disorder, and although most recover completely, some patients require extended treatment with antiarrhythmic agents, cardiac pacemaker placement, inotropic agents, or intra-aortic balloon pump. In patients with prolonged cardiac instability, cardiogenic shock and death are common, despite maximal therapeutic intervention.

Abdominal Injury

Perspective

Serious abdominal injury accounts for approximately 8% of admissions to pediatric trauma centers. Abdominal trauma is the third leading cause of traumatic death in children after head and thoracic injuries. Abdominal trauma is the most common cause of unrecognized fatal injury in children. Pediatric abdominal trauma results from blunt causes in the vast majority of cases. Of patients presenting primarily for other associated injuries, 9% die from abdominal trauma associated with these injuries.

Blunt trauma related to MVCs causes more than 50% of abdominal injuries in children and is the most lethal. “Lap belt” injury, including small bowel injury and Chance fractures, may occur in approximately 5 to 10% of restrained children involved in MVCs. Another common cause of abdominal injury involves bicycle crashes. Handlebar injuries represent a serious cause of injury and subsequent hospitalization for the pediatric population; patients requiring admission have a mean hospital stay greater than 3 weeks. Often, the effects of bicycle injuries may not be seen on initial presentation, with the mean elapsed time to onset of symptoms being nearly 24 hours after injury. All children with epigastric pain after blunt trauma, especially when concentrated force has been applied in this area, should be considered to have duodenal hematoma until proven otherwise. Pancreatic injury, including transection, should be strongly considered as well.

Sports-related injuries are another common cause of pediatric abdominal trauma. Sports-related injuries are associated most commonly with isolated organ injury as a result of a blow to the abdomen. At particular risk are the spleen, kidney, and intestinal tract in children. Finally, significant abdominal injury occurs in only approximately 5% of child abuse cases, but it is the second most common cause of death in these cases, following deaths resulting from head injury.

Principles of Disease

The anatomy of the child lends special protection from some abdominal injury patterns and predisposes the child to other types of injuries in blunt and penetrating abdominal trauma. Children have proportionally larger solid organs, less subcutaneous fat, and less protective abdominal musculature than adults and relatively more solid-organ injury from blunt and penetrating mechanisms. Children have relatively larger kidneys with fetal lobulations that predispose them to renal injury. Children also have a fairly flexible cartilaginous rib cage that allows for significant excursion of the lower chest wall, permitting compression of the internal organs. The combination of these factors provides the basis for the differences in abdominal injury patterns seen between children and adults.

Clinical Features

Pediatric patients with multiple injuries often present with blunt abdominal injury. In children, history is often limited, traditional signs of decompression seen in adults are often not as evident, and physical examination can be difficult. Subtle, early abdominal findings may be overlooked, leading to significant morbidity and mortality. The history and examination of young children who have sustained trauma is challenging because it may be difficult to know if the child hurts “all over” or has focal findings. The emergency physician may use distraction with toys, lights, bubbles, or keys to get the child’s mind off the examiner and onto the distraction; in this way, areas of tenderness may be located. Child life specialists can assist in distraction techniques, allowing the physician to better concentrate on subtle signs of injury.

Signs and symptoms of abdominal injury in children include tachypnea from impaired diaphragmatic excursion, abdominal
tenderness, ecchymoses, and signs of shock. Lutz and co-
workers demonstrated that among restrained children involved in MVCs, those with abdominal bruising were much more likely to have an intra-abdominal injury than those without bruising. One in every nine patients with ecchymosis was found to have an intra-abdominal injury, some requiring surgery. Abdominal distention is a common nonspecific finding that is often the result of air swallowing subsequent to a painful event. Children with hepatic and splenic injuries may have trouble localizing their pain. Kehr’s sign (left shoulder pain with spleen injury) may be the only indication of an intra-abdominal injury. Any abdominal tenderness on examination should prompt further evaluation of the abdomen. Vomiting is usually a late sign or one associated with duodenal hema-
toma or traumatic pancreatic injury. Signs of small bowel injury may be delayed and noted clinically only with serial examina-
tions. Pelvic bone stability and a rectal examination searching for signs of urethral injury (rare) in boys or blood in the stool (girls and boys) and spinal cord injury (girls and boys) may need to be performed in selected cases of trauma. Rectal examination is insensitive and nonspecific when used as a general screening test for all patients after serious trauma. Cases with suspected injury should receive further evaluation even when the rectal exam is unremarkable.

Even minor falls can result in significant splenic injury but with only minimal findings on examination. Repeated exami-
nation, prolonged observation, and close attention to vital signs are warranted. Any child with a clinically suspicious abdominal examination should be evaluated further with additional radiologic and laboratory studies and/or admission for serial examination.

Diagnostic Strategies and Management

In patients with suspected abdominal injury or with mecha-
nisms of possible injury, management and resuscitation must be rapid. Because of fear and pain, children can compound the difficulties in the management of serious penetrating or blunt abdominal trauma. Children tend to distend the stomach greatly with ingested air, which can decrease the diaphrag-
matic excursion. This can compromise respiratory efforts, and early decompression via NG or OG tube insertion should be considered. Children with a stable pelvis and who are not at risk of urethral trauma should have a urinary catheter inserted to decompress the bladder, evaluate for the presence of urinary retention, and examine for the presence of blood in the urine. The bladder should be decompressed before any invasive evaluation of the abdomen, such as DPL, to prevent accidental laceration during the procedure. A rule of thumb for urinary catheter size in children is 5 F in newborn, 6 F in preschool, 8 F in elementary school, 10 F in middle school, and 12 to 14 F in high school.

DPL and diagnostic peritoneal aspiration are occasionally still useful in modern trauma practice. In the unstable multi-
trauma patient with an equivocal FAST exam, the aspiration of 10 cc of blood, fecal, or vegetable matter from the abdomen typically would indicate intraperitoneal hemorrhage and/or bowel injury and the likely need for laparotomy. The DPL has less use in today’s practice but is performed by placing 15 cc/ kg of NaCl in the peritoneal space and then removing the fluid by gravity. In blunt trauma, a positive DPL is defined as having greater than 100,000 red blood cells/mL or greater than 500 white blood cells/mL, or gram-negative bacteria or vegeta-
tive material (stool) seen on microscopy. DPL does not evalu-
ate for retroperitoneal bleeding. The threshold values must be lowered for penetrating trauma. In general, DPLs are not per-
formed on stable patients because CT scanning can be done quickly and give the clinician far more information, especially about intraparenchymal injury and retroperitoneal injury. CT scanning is not very sensitive for bowel injury and results in significant radiation exposure. This must be kept in mind in decision making and when interpreting test results.

Spleen Injury. Injuries to the spleen are the most common inju-
ries in pediatric abdominal trauma. Children with injuries from MVCs, sudden deceleration injuries, and contact sports–related injuries may sustain splenic trauma. Typical findings include left upper quadrant abdominal pain radiating to the left shoul-
der. The abdominal examination may show evidence for peri-
toneal irritation in the left upper quadrant of the abdomen. Patients may be hemodynamically stable or, after significant splenic rupture or laceration, may be persistently hypotensive or in fulminant cardiovascular collapse. Stable patients may undergo CT for radiologic evaluation. Most often, with minor splenic trauma, bleeding is controlled spontaneously without operative intervention; however, all patients with a splenic injury should be evaluated by a surgeon. In cases with a contained splenic subcapsular hematoma, extracapsular bleeding may occur days later. Patients with splenic injury should be admitted to the hospital for close observation and repeated examinations.

Liver Injury. The liver is the second most commonly injured solid organ in the pediatric patient with abdominal trauma. However, it is the most common cause of lethal hemorrhage, with a mortality of 10 to 20% in severe liver injury. Mechan-
isms of injury causing splenic injury also may cause liver trauma. Tenderness on palpation of the right upper quadrant of the abdomen and the complaint of abdominal pain in this region or in the right shoulder are signs of possible liver injury. Patients managed conservatively often do well; however, patients who are initially treated conservatively but then go on to require delayed laparotomy often have signifi-
cant morbidity and mortality. Close observation in the hospi-
tal, serial abdominal examinations, and serial hemoglobin are recommended.

Renal Injury. The kidney is less susceptible to trauma from forces applied to the anterior abdomen, but it is often injured in the pediatric patient with multiple injuries. Because this organ is retroperitoneal, signs and symptoms of kidney injury are often less obvious and more diffuse than signs and symp-
toms of other abdominal organ injuries. Often, dull back pain, ecchymosis in the costovertebral region, and hematuria are the only clues to renal injury.69,70 Renal ultrasound and CT may be used in a stable patient to assess the degree of renal involve-
ment. Other organs, such as the pancreas and gastrointestinal tract, are less frequently injured in pediatric patients.

Penetrating Injury. Penetrating wounds to the abdomen usually require rapid evaluation by a surgeon and, in some cases, operative intervention. The role of DPL in the management of pediatric trauma is controversial. DPL provides the most rapid, objective evaluation of possible intraperitoneal injury. Patients who remain unstable despite fluid resuscitation may be candidates for DPL if they are too unstable for CT and there are multiple potential sites of blood loss. An important role for DPL is in the setting of an underlying small bowel injury. In some patients with small bowel injury, CT findings of free fluid may be ascribed improperly to underlying splenic bleeding. Finally, DPL may be considered in the operating room for patients undergoing emergent craniotomy, when adequate evaluation of the abdomen cannot take place because of the urgency required for intervention for head injury.

Radiology. Because pediatric patients suffer more from injury to the spleen, liver, kidneys, and gastrointestinal tract, CT of the abdomen can provide high sensitivity (except with intestinal injury) and specificity for identification of these
injuries while being relatively noninvasive. Recent studies have clarified that oral contrast does not add to the accuracy of CT; thus, one can avoid delays in evaluation, difficulty with administration, and risk for aspiration.

Another useful procedure in an acutely traumatized pediatric patient is bedside abdominal ultrasound. When used by an experienced clinician, ultrasonography can provide sensitive information about intraperitoneal hemorrhage without invasiveness measures. Although radiologic evaluation can provide important diagnostic information in a pediatric patient with possible abdominal trauma, any patient with unstable vital signs from an obvious surgically correctable cause should receive immediate operative intervention and not be subjected to delay while obtaining radiographic screening studies. Children with persistent or recurrent hypotension, continued abdominal pain, or persistent abdominal distention should have expedient evaluation by a surgeon.

**DISPOSITION**

A key decision for the emergency physician is whether to admit a pediatric trauma patient or transfer the patient to a tertiary care facility. The decision for admission in questionable cases should be based on consultation with the surgeon and the patient's primary care physician. Infants and children who are moderately to severely injured have improved outcomes in a pediatric (specific) ICU versus an adult ICU or an adult ICU with a few segregated pediatric beds. The primary role of the emergency physician is to evaluate and stabilize the patient before admission to a pediatric ICU or before transfer to a tertiary care facility. Before transport, it is vital that the child is appropriately stabilized and that the emergency physician communicates directly with the accepting physician at the accepting facility. Extensive radiologic testing should generally not be completed in a facility that cannot potentially manage that which is being looked for unless the emergency physician is confident that it will not delay the transfer to more definitive care and has discussed the plan with the receiving physician. All radiographs, documents, and results of laboratory testing should be sent with the patient. Parents should be informed of the exact location to which the child is being taken and given a map from the transferring facility to the receiving facility. Under no circumstances should the child’s likely outcome be downplayed to the patient’s parents before transfer because this leads to false expectations and the assumption of poor care if the outcome promised is not achieved.

Indications for admission are many, but the main criterion is to admit patients requiring ongoing monitoring for deterioration or complications of their injuries. In addition, children with suspected physical injury from child abuse may be admitted for their protection and for medical treatment. The threshold for admission should be very low in cases in which the health care team does not believe the child will have the social support or oversight necessary to be appropriately observed or to recover in the home environment. The family should be asked if they have transportation, a phone, and access to emergency medical service if needed.

**Cessation of Care**

Despite advances in trauma care and system improvement, some injured children will die—some in the emergency department. Cases in which death is certain or has already clearly occurred, such as with decapitation and findings of livor mortis or rigor mortis, do not present treatment dilemmas. Those who do present with signs of life (respirations, blood pressure, pulse, pupil reactivity, or cardiac and electrical activity) should have resuscitative efforts initiated. Cardiac echo can be helpful in some cases to confirm the lack of cardiac activity in patients without a pulse who continue to have electrical activity. Patients who lose their vital signs en route to or in the resuscitation room should receive maximum resuscitative efforts, potentially including emergency thoracotomy.

Operation should be considered part of the “Omega survey,” which is the final review after death is declared. Signs of maltreatment, congenital abnormality not previously recognized, possible personal identifying marks in unknown cases, and points for future education and study can be gained from one last mental and visual review, as can the potential for some insight related to the cause of death. Operation should be offered under local and state guidelines to all families of deceased children. Often, it is viewed as one way parents can make sense of the death of their child. Knowing that their child’s death helped many others to live can help parents in their healing.

Parental presence should be considered in all pediatric resuscitation cases. Assigning someone to be with the parents to explain what is happening is essential. Often, the parents’ presence can be useful to the resuscitative effort. Information can be obtained immediately when needed from the parents, and they witness the effort that goes into trauma resuscitation. Very rarely, parental presence can present a true hindrance to medical care, in which case the parent can be asked to leave or be escorted out of the room. Parents who witness what the team does for their children during resuscitation seem to better understand the ability and limitations of medicine. In the final analysis, most parents want to be there, and frankly, at the time of death, their presence is more important than the presence of the medical team.

**KEY CONCEPTS**

- Trauma is the leading cause of death in children in the United States. It accounts for 64% of all deaths in children, totaling 1.5 million injuries and 250,000 hospitalizations annually.
- Proper management of a pediatric trauma patient involves most of the components of standard adult trauma protocols. By paying strict attention to the anatomic and physiologic differences in children, the clinician is assured of the best patient outcomes.
- The leading cause of traumatic shock in children is hypovolemia; management priorities include appropriate ventilation and oxygenation and fluid resuscitation to maintain perfusion.
- The diagnostic test of choice for the evaluation of intra-abdominal injury in a stable patient is CT of the abdomen.
- Controlled hyperventilation should be performed on children with signs of impending brain herniation, and Po2 levels should be maintained at 30 to 35 mm Hg to avoid secondary brain injury from excessive hyperventilation and subsequent cerebral vasoconstriction.
Background
At the beginning of the 21st century, nearly 13% of the population in the United States was older than 65 years, and by 2040 one in five people will be within this age range.1 The financial impact of this aging has been tremendous and will continue to accelerate. The first baby boomer became eligible for Social Security on January 1, 2008, and it is estimated that 365 baby boomers will reach retirement age every hour. More than 35% of total health care dollars spent in the late 1990s was for medical care for patients older than 65 years, and undoubtedly this percentage will continue to rise.1

With regard to trauma, elders (patients older than 65 years) account for only 10 to 14% of all victims, but they consume 25 to 33% of trauma-related health care dollars. Injury is the fifth leading cause of death in this age group2 because of a combination of physiologic changes that alter the older patient’s response to trauma and injury mechanisms and patterns that are demographically different from those of younger trauma patients. Even among patients older than 65 years, risk stratification exists. Although the risk of death and significant injury is increased in patients 65 to 80 years of age, traumatized patients older than 80 years are four times more likely to die from their trauma than are younger patients.3,4 Emergency practitioners must familiarize themselves with these differences among traumatized elder patients as well as understand the differences in resuscitation and stabilization of these patients.

Epidemiology
In younger patients, assault and motor vehicle crashes (MVCs) account for the vast majority of traumatic injuries. In elders, the most common cause of injury is falls,4,5 followed by MVCs, pedestrians struck by cars, and assaults.4 In general, elder patients are more likely than younger patients to be injured as a result of activities of daily living.

Falls
Falls are the most common mechanism of injury in elders, accounting for 40% of trauma in patients older than 65 years, and they are the leading cause of injury-related death in this patient population.4,5 One third of elder patients suffer a significant fall each year, and serious injuries occur in up to one fourth; this rate is increasing rapidly.5,6 Risk factors for falls include medications (sedatives in particular), cognitive and visual impairment, history of stroke, and arthritis. Most falls occur at home and are same-level falls (i.e., falls from the standing position). Because as many as a one fourth of these falls occur as a result of an underlying medical problem,7,8 an appropriate medical evaluation is indicated in addition to the trauma assessment and stabilization. Some of the medical causes of falls include strokes, syncope, near-syncope, medications, elder abuse, and hypovolemia (e.g., related to gastrointestinal bleeding, ruptured abdominal aortic aneurysm, sepsis, or dehydration).

The most common injuries sustained in falls are fractures, occurring in 5 to 10% of fall victims.5,6 Up to 10% of patients may sustain a major injury,7 and head injury is the most concerning of these. Many elder patients are on anticoagulants; this makes them more susceptible to significant head injury as a result of a fall. Some studies have shown the incidence of trauma-related abnormalities on head computed tomography (CT) scans in this group of patients to be as high as 16%, with 1 in 50 requiring neurosurgery.10 The most common abnormal head CT finding is a cerebral contusion, followed by subdural hematoma; epidural hematomas are rarer in elder patients than in younger patients. The greater the height of the fall, the more likely the patient is to have an abnormal CT scan, but serious head injuries may also be seen in patients who suffer a same-level fall. Overall, the peri-injury mortality rate in elders from falls approaches 12%, and up to 50% die within 1 year of the fall,9 often related to either recurrent falls or significant medical complications.

Motor Vehicle Crashes
MVCs are the second most common cause of trauma in elders, accounting for 20 to 59% of trauma in this age group.4,11 Compared with younger patients, older drivers are more likely to be killed or hospitalized because of an MVC even when they are using seat belts.11 Cognitive impairment, decreased hearing and vision, and slower reaction time are significant risk factors for MVCs in this age group.

Most MVCs involving elders are daytime crashes occurring close to home. These crashes often occur at an intersection and usually involve two cars.11 An elder is twice as likely as a younger person to be in an MVC when making a left-hand turn, and injuries sustained in these broadside crashes tend to be more severe. A single-vehicle crash should raise suspicion of a medical problem that may have caused the crash and requires a careful history, examination, and workup. MVCs in
elders are less likely to involve alcohol, excessive speeds, or reckless driving than those involving younger patients. The overall fatality rate among elder MVC victims is as high as 21%.4,11

Auto versus Pedestrian Incidents

The third most common cause of injury in elders is auto versus pedestrian incidents.4 As with MVCs, poor eyesight and hearing, as well as decreased mobility and longer reaction times, make pedestrian elders more likely than younger patients to be hit by a motor vehicle. This mechanism accounts for 9 to 25% of trauma in elders and carries the highest fatality rate, reported to be from 30 to 55%.4

PRINCIPLES OF DISEASE

Physiology and Pathophysiology

Physiologic changes are inevitable with aging. These changes affect the mechanisms of trauma, types of injuries sustained, response to injury, approach to resuscitation, and prognosis for the injured elder patient.

Compared with younger patients, elders have a more severe injury response to any given trauma mechanism and have a decreased ability to respond to the trauma. In addition, preexisting medical problems may be exacerbated by the trauma, and morbidity and mortality may result from underlying diseases such as cardiovascular or cerebrovascular disease rather than the trauma.

Elders are less likely to be involved in reckless trauma than their younger counterparts. Diminished hearing and sight increase the risk of falls, pedestrian injuries, and traffic collisions. Difficulty with gait and coordination because of impaired sensation and proprioception, muscle weakness, degenerative joint disease (DJD), neuromuscular disorders, and dementia lead to increased risk of falls and affect reaction times in pedestrians and MVCs. Finally, medications have a significant impact on the traumatized elder patient. Medications that may alter mental status (sedatives and antidepressants) make the elder patient more susceptible to traffic collisions and falls. Cardiovascular medications affect the response to hypovolemia and shock as well as resuscitation. Diuretics may lead to volume contraction before the trauma occurs. Profound hypokalemia secondary to diuresis can also cause weakness and an impaired ability to ambulate or effectively operate foot pedals. Anticoagulants clearly affect the risk of bleeding. Many elder patients are taking these medications; studies show that the most commonly prescribed medications in the elderly are diuretics, cardiac agents, psychotropic drugs, and anticoagulants.12,13

Cardiovascular System

Cardiovascular reserve decreases with age, and because the aging heart cannot easily increase cardiac output (the maximum achievable heart rate decreases with age), elders tend to respond to hypovolemia with increased systemic vascular resistance. In addition, they are less responsive to the increased circulating catecholamine response to shock, making them at risk for earlier decompensation from hypovolemia. Medications such as antihypertensives may affect their ability to increase systemic vascular resistance, and beta-blockers, calcium channel blockers, and digoxin decrease their ability to develop a tachycardic response to shock. Underlying coronary artery disease increases the risk of myocardial ischemia from hypotension and blood loss. Overall, elders are less able to respond to fluctuations of blood pressure and blood volume that may accompany a traumatic injury than are younger patients, and these changes may exacerbate underlying cerebrovascular and cardiovascular disease.

Pulmonary System

Aging significantly affects the pulmonary system. Reductions in arterial partial pressure of oxygen (PaO2), forced expiratory volume in 1 second (FEV1), and vital capacity occur with aging; the lungs become less compliant; and the muscles of respiration weaken. As a result, elders are less tolerant of the volume resuscitation and spinal immobilization that are often needed in resuscitating a trauma victim. In addition, the chest wall is more brittle because of osteoporosis and more rigid because of DJD, making injuries to the chest wall more likely in an elder patient. Combined with the decreased pulmonary reserve in elders, chest wall injuries may quickly lead to respiratory failure in this population of patients. Elders are therefore more likely to require intubation after trauma and are more difficult to wean from respirators after intubation.

Central Nervous System

With aging, the dura mater adheres to the inside of the skull, making epidural hematomas rarer in elders than in younger patients. With age, the brain often atrophies, making it more mobile within the skull during trauma. This atrophy and the resultant stretching of the bridging veins seen in elders make them more susceptible to subdural hematomas than younger patients, even with seemingly minor mechanisms of injury or minimal external evidence of trauma.

Skeletal System

Osteoporosis, a common condition in elders, is a significant risk factor for skeletal injuries such as compression fractures of the thoracic and lumbar spine and other injuries including hip and wrist fractures. These injuries may occur even with relatively minor trauma. Decreased mobility of the joints is also a problem, particularly in the spinal column. This limited mobility increases the risk of spinal injuries, and the locations of these injuries differ in the elder patient. Spinal stenosis, more common in elders than in younger patients, increases the risk of spinal cord damage even in the absence of spinal column injury.

Skin

Skin trauma is common in the elder patient. Aging skin thins and is susceptible to tears and lacerations even with relatively minor trauma. These injuries may be very difficult to repair and often require débridement of devitalized tissue. Prolonged immobilization on a backboard or in a C-collar can result in decubitus ulcers of the back, buttock, or occiput. In addition, elders may be prone to tetanus due to lapses in their active tetanus immunization.

SPECIFIC DISORDERS AND INJURIES

Perspective

Multiple trauma in the elder patient is more lethal than in younger patients; a multiply traumatized patient 70 years of age is three times more likely to die than a patient 20 years of age.4 The combination of comorbid illnesses, increased propensity to trauma, and decreased physiologic reserve often
leads to exacerbation of underlying medical problems and a higher risk of multiple-system organ failure and death in the elder patient.14

**Spinal Injuries**

Physiologic changes with aging predispose the traumatized elder patient to both spinal column and spinal cord injury. DJD leads to decreased spinal mobility and a more brittle spinal column, and osteoporosis makes the bones more likely to fracture. Spinal stenosis often occurs as a result of the aging process; this increases the risk of cord injury even in the absence of a bone injury. Baseline cognitive impairment or acute brain injury may make evaluation of the spine in an elder trauma patient particularly difficult.

The most common mechanism of spinal injury in an older person is a fall. Because of the relative immobility of the cervical spine related to DJD, the most common level of cervical spine injury in elders is C1 to C3, a higher level than in younger patients. The most common fracture of the cervical spine in elders is a type 2 odontoid fracture, which necessitates adequate visualization of this area of the cervical spine when imaging is performed, often requiring CT scanning with reconstruction. Even if the patient does not suffer a fracture, spinal cord injuries may result from contusion of the cord. Contusion occurs most frequently in hyperextension injuries leading to central cord syndrome (upper extremity greater than control). Ischemic spinal cord atrophy from cervical spine injuries in elders is subacute and an isodense lesion is suspected. When the injury is subacute and an isodense lesion is suspected, a fracture is unlikely, and these patients may need admission for adequate pain control. It may also be necessary to differentiate compression fractures from burst fractures, and CT is often helpful in making this distinction.

**Head Injuries**

Head injuries are the most common cause of mortality directly related to trauma in elder patients. The most common mechanism of significant head injury in elders is falls. Epidural hematoma is rare because of the adherence of the dura mater to the inside of the skull. Cerebral contusions, however, occur in up to one third of head-injured elder patients, and subdural hematomas become more common with age because of the stretching of the fragile bridging veins as the brain atrophies. This atrophied brain is more mobile within the skull, and head trauma may result in shearing of these veins. These patients may present with a broad range of symptoms, from frank coma to a relatively remote history of head trauma and slightly altered mental status.

Mortality from head injury in elders is double that of younger patients, with mortality from subdural hematoma in elders being up to four times higher than in younger patients.20 When patients have minor head injury, elders may eventually recover full function but often need either in-hospital or home rehabilitation before they can return to their baseline function.

Head CT scanning is the diagnostic test of choice for brain injury, and a contrast study may be necessary if the injury is 7 to 20 days old and an isodense subdural hematoma is suspected. Magnetic resonance imaging (MRI), if available, is an alternative imaging modality in these patients when the injury is subacute and an isodense lesion is suspected.

**Chest Injuries**

Rigidity of the chest wall related to DJD and osteoporosis makes chest wall injuries more common in elders, even with relatively minor trauma. Because of the frailty of the chest in these patients, lap and shoulder belts in automobiles may actually cause injuries, including multiple rib fractures, flail chest, and sternal fractures. Rib fractures are the most common, and because elders have less pulmonary reserve than younger patients, these fractures may lead to respiratory insufficiency. Elder patients more frequently develop respiratory failure from their trauma and are more likely to require mechanical ventilation. In addition, elders may develop atelectasis, pneumonia, and acute respiratory distress syndrome. With proper care (including pain medication), meticulous attention to pulmonary hygiene, and careful hemodynamic management and monitoring, up to 90% of patients with chest injuries may return to normal life after their injuries.

**Abdominal Injuries**

Depending on the mechanism of injury, up to 30% of elder trauma patients may suffer a significant intra-abdominal injury, but the abdominal examination may be unreliable in these patients. Because mortality from abdominal injuries in elders is four or five times higher than in younger patients, a diligent search for potential intra-abdominal injuries is crucial. Frequently, this requires some combination of focused abdominal sonography in trauma exam (FAST) and CT scanning of the abdomen, depending on the patient’s hemodynamic stability and other system injuries.

**Extremity Injuries**

Because of the increased bone fragility and predisposition to falls with aging, the musculoskeletal system is the most commonly injured organ system in elder trauma patients. By the age of 75 years, 30 to 70% of patients with osteoporosis sustain a fracture.22 Although rarely life threatening, these injuries can severely limit the daily activities of elder patients to the degree that these patients may need admission for pain control as well as to arrange adequate home support or rehabilitation.

Upper extremity fractures are common. Distal radial fractures are the most common upper extremity fractures in elders, accounting for up to 50% of fractures, followed by proximal humeral fractures (30%) and elbow injuries (radial head fractures and elbow dislocations; 15%).

Pelvic fractures are common in elder trauma patients, accounting for 25% of these injuries.23 Pubic rami fractures, the most common pelvic fractures in this age group, may be seen with same-level falls. Although these injuries tend to be stable, pain control and gait training may necessitate hospitalization. High-velocity injury mechanisms (MVCs or auto versus pedestrian incidents) and falls from heights may result in unstable pelvic fractures, which are associated with a mortality of up to 80% if the fracture is open.

Hip fractures are the most frequent lower extremity fractures and the most common cause of admission in elder trauma patients. These injuries are associated with an early mortality rate of 5% and a risk of death of 13 to 30% during the year after the injury (often related to other factors, such as recurrent falls and underlying medical problems). Plain radiographs are often diagnostic, but CT or MRI scanning may be necessary to discover or further delineate subtle fractures in the elder patient with hip pain after a fall.

Tibial plateau fractures may occur with a fall or MVC and most commonly involve the lateral tibial plateau. Patellar frac-
tutes may result from a fall directly onto the kneecap, and sunrise views of the patella may be the only way to visualize these injuries. Ankle fractures account for 25% of all lower extremity fractures and most commonly involve the lateral malleolus; treatment often consists of a walking cast.

**Soft Tissue Injuries**

Elder patients are susceptible to skin injuries related to the thinning of the skin that occurs with aging. Treatment of these injuries often proves to be difficult, and débridement of devitalized tissue and careful local care are often necessary. Elder patients frequently are not up to date with their tetanus immunizations and because of this are at risk for developing this infection. Treatment with both active and passive immunization is often indicated in this group.

**Burns**

Burns are particularly devastating in the elder patient. More than 90% of burns occur at home, and because elder patients often live alone and have decreased reaction times, deeper and more extensive burns may occur in this age group. Flame burns account for 50% of all burns in this group and 20% of burn-related deaths. Some of these injuries are cooking related; scalds account for 19% and flammable liquid burns for 10%. Despite the fact that the incidence of burns is lower in elders than in younger patients, mortality from this injury is high. Until the mid-1980s, Baux’s formula (risk of mortality = age in years + percentage body surface area burned) provided a gross estimate of risk of death from burns. Although advances in burn care during the past two decades have decreased the mortality rate, elders are still at high risk for mortality from burns, with recent data suggesting a mortality rate of approximately 30%. Thinning of the skin and decreased immunocompetence contribute to this higher risk of mortality as well as exacerbation of underlying medical conditions that may be precipitated by the stress of an extensive burn injury and its treatment.

**CLINICAL FEATURES**

Because elder patients may have significant injuries with subtle findings, a thorough examination supplemented by laboratory testing and radiographic studies is often the most prudent approach to even seemingly minor injuries, depending on the mechanism of injury and the presence of comorbid conditions and particularly certain medications (e.g., anticoagulants).

**History**

A complete history of the events leading to the injury is needed, and out-of-hospital personnel can be invaluable in providing this information. Falls and MVCs, particularly if they involve a single vehicle, should trigger questioning about possible syncope, hypovolemia, cardiovascular or cerebrovascular events, or a complication of medications. The mechanism of injury should be considered and the different patterns of injury in elder patients evaluated (e.g., higher risk for subdural hematoma, high cervical spine injury, and bone injuries).

**Physical Examination**

In patients with anything more than the most minor of mechanisms of injury, a thorough head-to-toe examination should be performed. Clothing should be removed in order to allow a complete physical examination. Vital signs may be normal, even in the presence of significant blood loss. Because many elder patients are on antihypertensives, normal blood pressure may in fact signify the presence of hemorrhage. It is important to keep elder trauma patients warm because they are more likely to develop hypothermia when disrobed for examination, and hypothermia increases the risk of mortality related to trauma.

**DIAGNOSTIC STRATEGIES**

**Laboratory**

Laboratory evaluation should include serial hemoglobin, hematocrit, or both; prothrombin time and partial thromboplastin time and an international normalized ratio; serum electrolytes; rapid and formal glucose measurements; and medication levels if indicated. An electrocardiogram is also useful to evaluate the patient for a precipitating event as well as to assess any cardiac ischemia that may be caused by the trauma and resultant injuries.

**Radiology**

Radiographic studies should be ordered as indicated by the history and physical examination. Plain films of the cervical spine are often difficult to interpret because of baseline DJD; therefore, CT scans of the neck, with particular attention to the more likely injured higher cervical spine, may be necessary to rule out spinal injury. This is particularly true if clinical findings warrant and plain films are inadequate or demonstrate suspicious areas. Plain films of the thoracic and lumbar spine should be obtained in patients with posttraumatic pain in these areas. A chest radiograph may be of particular importance both to evaluate the patient for traumatic injuries and to search for signs of congestive heart failure precipitated by the trauma or resuscitation efforts. Plain films of the pelvis are indicated in patients with suggestive mechanisms of injury or pain on examination of the pelvis. Extremity films should include all areas of concern, and CT or MRI scanning may be necessary to diagnose subtle hip fractures. Adequate radiographic imaging to rule out significant intra-abdominal injury may require FAST, CT scanning, or both, depending on the clinical presentation of the patient.

**MANAGEMENT**

**Prehospital Considerations**

Because elder patients may have significant injuries even with minor mechanisms of injury, prehospital management is particularly important. Scene assessment is important because prehospital personnel are often the “eyes and ears” for assessing the mechanism of injury, and this information should be solicited from prehospital personnel by emergency department staff. Rapid transport to the hospital is of prime importance. Because elder trauma patients are more likely to suffer significant injuries after even relatively minor events, transportation to a trauma center should be considered for elders who sustain anything more significant than isolated extremity trauma.

**Emergency Department**

Emergency department assessment of elder patients requires an organized and rapid evaluation for significant injuries and
frequent reassessment to identify deterioration early. Frequent monitoring of vital signs and maintaining a normal core temperature are important in the management of elder trauma patients.

Airway and Breathing

Supplemental oxygen should be administered to all elder trauma patients. Pulmonary insufficiency may develop quickly, and airway management equipment must be readily available. Airway management may be particularly difficult in elders, and potential problems should be anticipated. Cachectic or edentulous patients may be difficult to ventilate with bag, valve, and mask. Decreased mouth opening and limited neck mobility related to DJD may interfere with orotracheal intubation, and preexisting medical problems such as cerebrovascular accidents or renal failure may alter the choice of neuromuscular blocking agents used to facilitate intubation. Dosing of any agent that may affect cardiovascular stability must be carefully considered, and administering lower doses of these drugs is prudent.

Circulation

Fluid and blood resuscitation is particularly challenging in the elder trauma patient. Underlying congestive heart failure may be exacerbated by aggressive circulatory resuscitation, but hypotension and hypovolemia are poorly tolerated, particularly in patients with cardiovascular or cerebrovascular disease. Elder patients who go to the operating room before hemodynamic stabilization have an extremely high mortality rate. The most prudent approach is controlled boluses of warmed isotonic fluids with frequent assessment of physical examination, vital signs, pulse oximetry, and urine output. Hypotension is often an ominous finding and should be corrected, with attention to the potential effects of large fluid volumes on the respiratory system. Normotension in the usually hypertensive patient may be a subtle indication of hemorrhage. Blood transfusion should be strongly considered when the hematocrit drops below 30, and there should be a diligent search for potential sites of blood loss.

Disability

Underlying hearing deficits and residual neurologic deficits from stroke, such as aphasia, motor deficit, or slurred speech, can make assessment of mental status and evaluation for neurologic injury problematic. Information on previous history of deafness or stroke or other neurologic disease should be obtained quickly from the patient or family or both, and an assessment should be made of whether the patient’s current condition represents a new or old finding.

**DISPOSITION**

Typical criteria for admission related to traumatic injuries apply in elders, but other considerations often lower the threshold for hospitalization. If the patient does not have a support system or home situation amenable to careful observation and recovery from even relatively minor injuries, hospital admission may be required. Patients with significant underlying diseases may need admission for monitoring and reassessment until their injuries begin to heal. Often, elder patients may need admission for pain control, particularly those with compression fractures of the spine or pubic rami fractures who may require frequent doses of narcotics for pain control. The use of narcotics can have additional adverse effects for elders that may put them at risk for additional injury, such as postural hypotension or confusion. Chest injuries may be particularly problematic and susceptible to complications, and elder patients with multiple rib fractures (three or more) or one or more displaced rib fractures should be admitted for aggressive pain management and supportive care. In addition, patients with multiple displaced rib fractures may be at risk of delayed death (24–48 hours) from exsanguinations due to severed intercostals vessels. Elders with minor injuries, particularly extremity injuries, may be discharged with appropriate follow-up care and medications.

**KEY CONCEPTS**

- Elder patients are more susceptible to injuries than younger patients and have a higher mortality rate for any given injury.
- Mechanisms of injury are different in elders than in younger patients. Elder patients are more likely to sustain their injury from a fall, an MVC, or an auto versus pedestrian incident than from an assault.
- Physiologic changes that occur with aging alter the way in which these patients may manifest significant injuries as well as how they tolerate these injuries.
- Emergency physicians must remember that elder trauma patients may have suffered a medical event that precipitated their trauma, or vice versa, and evaluate patients accordingly.
- Resuscitation of elder trauma patients requires oxygen supplementation, a lower threshold for advanced airway control (endotracheal intubation), and aggressive but judicious fluid and blood resuscitation with frequent reevaluation.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The science of injury control is based on the concept that trauma is like a disease rather than just the consequence of fate or random occurrences. The principles of disease control are applied to injury as they are successfully applied to infectious diseases. Control of a disease as widespread and multifactorial as injury can occur only through broad interdisciplinary effort, including that of medicine, public health, policy makers, law enforcement, educated citizens, and others (Box 37-1).

Emergency medicine plays a pivotal role in the care of injured patients and in injury control. Approximately one third of all emergency department visits are for the care of injuries, representing 14.4 visits per 100 people. Injury is the leading cause of death for many age groups (Table 37-1). In 2004, 29.6 million people were treated in emergency departments for injuries, of which 93% were not admitted to the hospital. The medical cost of injury-related medical care in the United States is estimated to be $117 billion annually. The emergency care system may be the patient’s only interface with the health care system. In addition to providing state-of-the-art acute care, emergency physicians should provide state-of-the-art clinical preventive services for these injured patients, as well as work with surgeons, pediatricians, and other specialists to decrease injuries through clinical and policy-relevant research and education.

Principles of the Disease of Injury

The major causes of injury include falls, car crashes, gunshot wounds, drownings, and poisonings. Similar to other disease models, injury occurs from the interaction of agent and host through a vector and an environment that is conducive to exposure (Fig. 37-1). Injury is a harmful event caused by the acute transfer of energy to a patient that results in tissue and/or organ damage. The energy may be in any form, such as kinetic (e.g., falls and motor vehicle crashes), thermal (e.g., burns and hypothermia), chemical (e.g., poisoning), electrical (e.g., lightning strike), or the absence of energy (e.g., hanging or drowning). Energy is the agent that is delivered to the host (patient) by a vector in an environment with variable risk. Cars and guns are examples of vectors of energy transmission that cause the injury. A car on an icy road is an example of the environment and the vector interacting to increase the likelihood of kinetic energy reaching the host and causing injury.

The goal of injury control, similar to other forms of disease control, is to prevent or decrease the transfer of energy to the host by (1) separating the host from the agent through modification of the environment, (2) equipping the host with protection against the agent, or (3) eliminating or modifying the vector that transmits the energy.

The first step in the control of injuries is the recognition that injury is preventable. Common public perception is that injuries are from accidents or random, unexpected events, similar to the way infectious disease was regarded before the discovery of bacteria. Similar to other diseases, characteristics of the host affect prevention strategies, acute care, and rehabilitation outcomes. These include physical characteristics, such as age, gender, size, and motor skills; and mental/behavioral characteristics, such as intelligence, fatigue, alcohol use and abuse, emotional stability, social norms, and lifestyle. Risks for injury and death vary by age (Table 37-1). To decrease the likelihood of an injury, changes in some of these predisposing factors can be made in the host (e.g., through improvement in driving skills or a commitment to wear a seat belt or not to drink and drive) and should be age specific for maximum effect.

Energy is transmitted to the host through a vector, such as motorized and nonmotorized vehicles (e.g., car, bicycle, and skateboard), firearms, piercing instruments (e.g., knife and arrow), explosives, and lit cigarettes. Modifying the vector (by elimination or modification of design) and separating the vector from the host are important methods to reduce injury. For example, understanding the biomechanical forces released during an injury event is crucial to understanding vehicle modification. This information can assist physicians in educating patients and families to modify or eliminate vectors they encounter during their daily lives—for example, recommending that families properly store and/or use gun locks with household firearms.

When an injury occurs, host–agent interaction and energy transfer take place in an environment. This environment can be modified to decrease injury. If the environment does not permit energy transmission, the risk for injury, including intentional injuries to the host (patient), is eliminated. In contrast to altering host risk factors, most environmental modifications require no cooperation or action on the part of the host and are more effective when implemented. Examples are implementing safer road design and lighting to prevent motor vehicle crashes, removing throw rugs to prevent falls, placing fences around pools, and separating bicycle paths and sidewalks from the roadway to protect pedestrians and bicyclists from cars.

William Haddon, the first physician administrator for the National Highway Traffic Safety Administration, first described
The epidemiologic triad can be used as a framework for injury prevention. An injury occurs by the interaction of the host and agent through a vector and an environment that is conducive to injury. Alteration of any of these interactions prevents the injury.11

The History of Injury Control and Emergency Medicine

The avoidance of personal injury is a goal of modern public health, but until the 1940s and 1950s, unintentional injuries were attributed primarily to human error, and prevention was based on educating people to act safely.10 Unsafe roads were built, and motorized vehicles and other consumer products were manufactured with safety design flaws.21 This is analogous to supplying untreated tap water to homes and relying on educating people to purify their drinking water to prevent cholera.11

In the 1920s, attributing vehicle crashes to poor driver performance led to mandatory licensing of drivers. In the 1930s, when it was realized that vehicle crashes were due not simply to human error but to mechanical factors as well, President Roosevelt called for automobiles to be made more crashworthy.8 In 1942, DeHaven, a former World War I pilot turned physiologist, pondering his own survival in an airplane crash when another occupant had been killed, suggested structural provisions be made to vehicles that would distribute the forces of energy over the human body to attenuate the energy transfer and reduce injuries in crashes. He advocated a focus on defining the physical factors that influence survival rather than the human error that caused the crash.8 Physical factors became a focus of interest as the United States embarked on its space program. Air Force researchers showed that people could withstand splashdown with a sled that decelerates from 30 to 0 mph over a stopping distance of 2 feet.22 This demonstration was a significant advance in understanding the biomechanics of sudden deceleration.

The recognition that injuries could be addressed similar to diseases occurred in the 1940s, when Gordon, an epidemiologist, suggested that injuries have epidemic patterns, seasonal variation, long-term trends, and demographic distribution and can be examined with methodologies applied to infectious diseases. Gordon also believed that similar to infectious diseases, injury results from the interaction of the agent, host, and environment.8 In the 1960s, Haddon developed a two-dimensional approach to injury analysis by dividing the factors of agent, host, and environment into three phases: preinjury, injury, and postinjury. This phase-factor matrix has become a mainstay of injury control development. Any injury event can be broken down into the component factors, allowing specific interventions to target specific factors (Table 37-4).12,23

In 1985, the publication Injury in America: A Continuing Public Health Problem by the National Research Council and the Institute of Medicine called on the public health and health care community to address the injury epidemic.13 With the establishment of the National Center for Injury Prevention and Control in the Centers for Disease Control and Prevention (CDC), it was acknowledged that the control of injuries belongs in the disease control community and includes health care providers such as emergency physicians.

Soon after its inception, the National Center for Injury Prevention began sponsoring injury control research centers at academic institutions throughout the country. These centers conduct research in all three core phases of injury control (i.e., prevention, acute care, and rehabilitation), and they serve as training centers for injury control specialists and as information centers for the public.24 In many places, these centers are led by physicians, including emergency physicians. To continue and expand this work, the Society for the Advancement of Violence and Injury Research was created, which is open to

In 2003, the National Center for Injury Prevention and Control began updating the CDC Injury Research Agenda to include acute care research, focusing on research that will improve acute injury care systems. Following this, the National Center for Injury Prevention’s Division of Injury and Disability Outcomes and Programs changed its name to the Division of Injury Response, whose mission is “to increase the capacity to prevent injuries and their adverse health effects by working with partners to develop, evaluate, and promote evidence-based surveillance, prevention, and care practices.” This center gives a home for acute injury care and acknowledges its importance for prevention. This division has also become a focus point for response to terrorist-related injuries, an important area of injury control.

### Methods of Prevention

The history of injury control began with the first injury. Pain from injury is a powerful stimulus for avoidance behaviors. Early prevention technology is seen in the instruments and garb of the earliest armies, shielding people from the harmful kinetic energy of weapons. Such technology included helmets, shields, and suits of armor. As the delivery of kinetic energy became more sophisticated, prevention technology did not keep pace. Firearms and automobiles represent new plateaus in harnessing kinetic energy as well as creating a new source of morbidity and mortality. The cultural belief was that individuals could avoid vehicular injury by safe driving, and if not, an “accident” occurred. It took more than 50 years to acknowledge that behavior modification alone was insufficient to mitigate high-energy transmission to persons in a haz-

ardous environment. Cars were not uniformly equipped with seat belts until the 1960s.21 It took another two decades before air bags became standard.15,16,28

Implementation of effective injury control strategies depends on collaborative efforts with physicians, nurses, out-of-hospital care providers, epidemiologists, biomechanical engineers, public policy makers, law enforcement officers, and lawyers.19,28,29 A major challenge is the wide diversity of disciplines and interests involved in safety and injury control, many of which are isolated from one another.19 In the 1990s, important strides were made in community-based injury control programs that rely on coalitions of existing resources with the support of the National Highway Traffic Safety Administration (NHTSA), the CDC, and the State and Territorial Injury Prevention Directors Association. These community coalitions were created to garner existing resources and implement injury countermeasures using “the 3 E’s” of public education, enforcement of laws, and engineering modification of hazardous devices and environmental conditions.19

**INJURY CONTROL IN MEDICAL PRACTICE**

Traditionally, physicians have focused on treating the patient after the disease has occurred. As the causes of many diseases have become increasingly understood, education about risk assessment and clinically based prevention has been integrated into medical practice, particularly in areas such as infectious (immunizations) and cardiovascular (smoking cessation) disease. Emergency physicians are incorporating risk assessment, counseling, and referral of patients in high-risk groups for injury, such as with domestic violence patients.10 The Joint Commission for Hospital Accreditation now has emergency department requirements for addressing abused patients.30

Emergency care providers are pivotal in the recording and accumulation of data about the injury event, which is useful for surveillance and epidemiologic analysis. Injury control techniques can be incorporated easily into emergency medicine practice as well.3,11,31 A rational approach to improve injury care in a community (Box 37-2) requires that emergency physicians, surgeons, pediatricians, and physiatrists assume specific roles and activities in promoting injury control. This role for emergency physicians in injury control has been advocated by the American College of Emergency Physicians.35 Documentation of injury information in the medical record, assessing risk factors in individual patients, counseling and referral, provision of systematized acute trauma care, and public health advocacy are all important.36-38

**Box 37-2  INJURY CONTROL IN EMERGENCY MEDICINE PRACTICE**

**Clinical Preventive Services**
- Document injury information in the medical record
- Ensure that medical records of injury cases contain E codes
- Assess behavioral and comorbid risk factors for future injury
- Provide risk screening, counseling, and referral
- Assess biomechanical risk factors in individual patients
- Use biomechanical risk factors for directed evaluation of injured patients
- Provide systematized acute trauma care

**Population Health, Research, and Policy**
- Participate in and advocate for inclusive trauma systems
- Direct and advocate for rapid, competent emergency medical services response
- Lead efforts in policy development, implementation, and evaluation
- Lead efforts in educating high-risk groups
- Lead efforts to address and modify the environment to reduce risk of injury
- Collaborate in multidisciplinary research to reduce injury risk and to improve care

**Injury Epidemiology and Documentation**

Gathering accurate data is essential to understand the characteristics of a disease—its endemic populations, cyclical variations, geographic characteristics, and effectiveness of interventions. Consistent and comprehensive data must be gathered across the population of injured patients to be used for research,39,40 hypothesis generation, ongoing monitoring of disease patterns and characteristics,34,41 and understanding outcomes of prevention and policy interventions. The goal of injury data collection is to discover who is being injured (host), what is injuring them (vector), and the circumstances surrounding the injury (environment).32,41

Until recently, good data on the disease of injury have been lacking, and knowledge gaps still exist.41 Before 1980, the only large civilian databases on injury available for study were mortality data collected by coroners and medical examiners. The Fatal Analysis Reporting System, a comprehensive data set on all car crash deaths in the United States, was established by the NHTSA in 197545 for examining the epidemiology of car crashes.

Because death results in only 1 in 1000 people who receive medical care for an injury, conclusions based solely on mortality data are limited.13,46 The advent of trauma registries in the 1980s increased the sample from patients who die to patients admitted to trauma centers. Because these data are skewed toward the most severe injuries, the conclusions based on these data may have limitations when generalized to the larger population of injured people.47

Approximately 93% of injured patients seeking medical care for injury are treated and discharged from the emergency department, many of whom experience significant morbidity resulting in long-term disability and significant cost to society.13,34,41,46 In recognition of the importance of emergency department data, the CDC developed Data Elements for Emergency Department Systems to define the minimum data set essential for physicians and information systems developers.34,49 The most crucial data element for the understanding of injury is the E code, a system for identifying the cause of injury in a patient’s medical record, according to a classification published in the International Classification of Diseases (ICD-9-CM).19 The “E” stands for external cause of injury, such as car crash, fall, or bicycle crash. The cause of injury cannot be extracted from diagnosis codes in medical records. These are “N” codes—the nature of the injury, such as skull fracture, laceration, or contusion. Because injury control depends on identifying the vector that is causing injuries and not just the resultant injuries, the only way to accomplish this systematically is by documenting the appropriate E code for each patient visit. Some states have mandated documentation of E codes for all emergency department discharges.34,41,43

The greatest barrier to the collection of E codes in the emergency department is inadequate physician documentation to assign accurate E codes retrospectively from the medical record.46,50,51 The first step in data gathering should be to completely and legibly document the cause of injury in patient medical records. Because injury problems in a community differ greatly from region to region, community-specific injury control efforts can be generated, implemented, and evaluated.19,40
E-coded hospital records can provide the *who, what, and when* of injury. The question of *where* can be either place of occurrence or place of residence, both of which are important and have implications for planned countermeasures. Hospital records are helpful in determining place of residence of injured patients, which is useful for community education in high-risk neighborhoods. Location-of-injury data are available only from other sources, such as emergency medical services (EMS), police, or other records. These data are more likely to be useful for environmental modification through engineering enhancements, police enforcement, or hazard removal. Linkage of these records to patient visits, either manually for specific research studies or electronically for surveillance, is the next step in gaining a comprehensive understanding of the epidemiology of injury.52,53 With the increasing availability of desktop computer-based geographic information system programs, this powerful tool can be used to study injury locations with minimal training and resources. The maps generated by these programs can be used to identify areas with injury clusters so that prevention efforts can be focused on areas with the greatest need.54,55

Statewide injury data linkages exist in some states and are available for surveillance information and research for unintentional and intentional injuries.54,32,40,43 For example, the Crash Outcome Data Evaluation System uses probabilistic linkage to create a database of crash, hospital, EMS, and emergency department information for motor vehicle crashes.55

Interest and opportunity to apply injury control principles are growing for medical injuries, also known as medical errors. Medical injuries account for an estimated 50,000 to 98,000 deaths each year in the United States, with hundreds of thousands of nonfatal events occurring in emergency departments, intensive care units, and operating rooms.54 Emergency physicians can play an important role in using injury control principles and science to reduce medical injuries.59-62 Application of injury control principles for the identification of injury patterns and for the development and evaluation of injury prevention strategies has great potential.61,62

**Risk Factor Assessment**

**Biomechanical Risk Factors**

Biomechanical factors responsible for the injury are challenging to understand, occurring in car crashes or gunshot in less than a 10th of a second. Emergency physicians are not trained in engineering principles and have had limited exposure to this “pathophysiology” during training. Ascertaining the forces released on the patient during a blunt (car crash or fall) or penetrating (gunshot or stabbing) injury leads to a directed approach to injury management.63-66 Extensive research has been done using crash dummies, mathematical models, and computer models to understand the mechanical forces applied in injury and human impact tolerance.68,69 Although used extensively by the engineering community for the design of products, such knowledge is also valuable to the emergency physician in guiding evaluation and treatment based on energy transfer, tissue tolerance, and risk of occult injury.7 Further, as this information becomes more readily available at the time of crash response through automatic crash notification (e.g., General Motor’s On-Star system), it will become more important to understand and correctly interpret what it means in terms of potential injuries.67

Injury occurs when energy is delivered to the host in levels that exceed tissue and organ tolerance. This energy can be expressed in G-forces. The G-force that results from a motor vehicle crash, for instance, can be expressed using the following formula:

\[ G = \Delta V^2 / (\text{stopping distance} \times k) \]

where \( \Delta V \) is the change in velocity, *stopping distance* is the distance over which the change in velocity occurs, and \( k \) is a constant. G-force is inversely related to stopping distance. To minimize energy transfer to the body during a car crash, one must maximize the stopping distance during the event. The formula shows that doubling the stopping distance reduces the G-force by half, but doubling the speed quadruples the force. Less G-force is applied as velocity is reduced over increasing distance, as the vehicle slows during pre-impact braking or deforms during a crash. The same principle underlies engineering features, such as interior padding, collapsible steering columns, water barrel barriers at bridge abutments, and flexible guardrails. All are designed to increase stopping distance, a major principle of automobile and highway safety engineering.15,16,68

The addition of the air bag to vehicles in the mid-1980s was a significant improvement in safety engineering because it resulted in increased occupant stopping distance during a crash. The NHTSA estimates that as of 2005, approximately 20,000 lives have been saved by air bags.69 Initially, these benefits were confined to frontal crashes, but the advent of side curtain air bags and their wide implementation has greatly contributed to the number of lives saved.70

As with many new safety countermeasures, there were unintended consequences. First-generation air bags deployed with tremendous force to protect unbelted occupants. These early air bags deployed aggressively at speeds of 140 to 200 mph over 50 msec.71 Such forces can be lethal to children in the front passenger seat, especially when unrestrained by safety belts, or seated in rear-facing infant seats.72,73 A new generation of advanced, less aggressive air bags has been used in the vehicle fleet since the late 1990s, which is expected to reduce injuries associated with air bag deployment. For an emergency physician to estimate risk when assessing a patient from a motor vehicle crash, it is essential to understand the differences in risk posed by seating position, restraint type and use, and vehicle type. This information also must be understood to counsel patients properly on safety belt and child restraint use.39,74

Understanding mechanisms of injury leads to more effective patient counseling to protect patients and their families against injury. Children less than 55 inches tall should only ride in the rear seats of vehicles. Infant seats should never be positioned in the front seat within range of the air bag. Infants 12 months old or younger and weighing 20 pounds or less should always ride in a rear-facing infant seat, and children older than 12 months and weighing more than 20 pounds should ride forward facing in a toddler seat. A booster seat should be used for children weighing 40 to 80 pounds, allowing for better seat belt positioning and discouraging the child from sitting out of position to see out the windows. If circumstances dictate that a smaller child must ride in the front passenger seat, that seat should be positioned as far to the rear as possible and a seat belt should always be worn.74 Federal rules allow for air bags to be disabled if there are circumstances necessitating that small children ride in the front seat and for certain medical conditions.75 Furthermore, increasingly more vehicles are equipped with sensors that turn off the airbag when certain weight thresholds are not met. Physicians caring for short-stature individuals should counsel these patients about the risk of air bag injuries and recommend they sit with at least 10 inches between the sternum and the steering wheel equipped with an air bag. This distance should be measured objectively because people tend not to estimate this distance correctly.76
Other safety features have been associated with specific injuries. Automatic “passive” shoulder belts that require manual fastening of the lap portion may result in “submarining” of the torso toward the floorboard when the lap portion is not fastened, while the shoulder belt squeezes the lower rib cage. Such a mechanism explains the association of these devices with liver, spleen, and lung injuries and has led to the discontinuation of these devices. However, since cars can be driven over a number of years, it takes many years to completely remove these dangers from the streets. Since automobile safety improves with each new model year, it is important to learn about these safety features and how they might change an injured patient’s presentation.

Knowing the contact surface in falls affects diagnostic and therapeutic interventions because soft surfaces increase stopping distance compared with concrete or packed earth. Understanding the biomechanical risks of other injuries, such as tissue forces from the ballistics of bullet wounds, can guide treatment decisions.

### Behavioral and Comorbid Risk Factors

Recognition of patients at high risk of injury affords opportunity for intervention. Counseling a patient about specific ways to avoid injury in the “teachable moment” after injury is more likely to have an effect than diffuse public education. Family or friends can be recruited to enforce the message to patients or to assist patients in modifying their behavior or environment. Other patient encounters may be used as an opportunity to counsel high-risk patients, such as children at developmental stages that put them at risk for auto versus pedestrian injuries, climbing injuries, or poisoning. It is particularly important to explore the circumstances surrounding injuries to children. A brief review of the injury incident would help physicians and parents identify risks for future injury and opportunities for intervention. Children who come to the emergency department for an injury are likely to be injured again, commonly during falls and motor vehicle crashes. Preschool-age children admitted to the hospital for injury were twice as likely as community controls to have been treated previously in the emergency department for injury and more likely to have been in the emergency department more than once.

Risk factors for intentional injury are complex and involve behavioral, social, and environmental factors, but risk factors for all types of injury include male, low income, illicit drug involvement, previous arrest, and young age. In studies using psychosocial inventories, recidivists are more likely to have a low sense of autonomy, to have low levels of spirituality, and to have been a victim of crime in the past. As a practical matter in the emergency department, the most obvious risk factor for future violent injury is prior violent injury. A history of prior significant injury is a strong predictor of injury recidivism, with 10 times the risk of patients with no prior trauma. Emergency departments should have protocols in place for the detection and referral of patients likely to be victims of injury in the future, including victims of domestic violence, and for children younger than 18 years injured intentionally, regardless of the age of the perpetrator. In many states, there are mandatory reporting laws for gunshot wounds, stabbing, and other violent acts. Interventions provided to injured patients in the health care setting can reduce injury recidivism.

In the case of motor vehicle injury, the three behavioral risk factors most likely to result in future injury are speeding, seat belt nonuse, and driving after drinking alcohol. Giving patients the necessary data for them to make an accurate self-assessment about their risks is the essence of patient behavioral intervention. These messages should be part of every injury patient’s encounter, when feasible. Particularly important in this context is the screening and referral for alcohol use disorders (AUDs). Alcohol-related crash injury is a national epidemic in the United States, claiming more than 17,000 lives annually and injuring an estimated 870,000 people. Reductions in alcohol-related deaths due to more stringent laws to curb impaired driving, more vigilant public education, and a societal shift toward the condemnation of driving while impaired have not had significant effects on people with AUD. Of patients seen in the emergency department after a motor vehicle crash, 17 to 20% meet criteria for AUD. Patients with AUD have higher rates of illness and motor vehicle crash injury than the rest of the population, and patients with AUD are more likely to drive after drinking.

Emergency physicians have a unique role to play in the identification of high-risk patients. In particular, patients with AUD should be detected and referred for formal evaluation and treatment. A structured approach to detect and treat the disease must be brief and effective if it is to be used in a busy emergency department. Screening techniques validated in the emergency department and methods of brief intervention have been thoroughly described.

Successfully treating AUD leads to reduction in alcohol consumption and, consequently, fewer impaired driving episodes, thus leading to a reduction in alcohol-related crash injuries. Evidence suggests that being treated for injury in the emergency department may be an important motivational opportunity to reduce drinking and presents a “teachable moment.” The American College of Surgeons’ Committee on Trauma recommends that all trauma centers screen for alcohol and provide interventions as a “part of routine trauma care.”

Motor vehicle crashes are the leading cause of death for children older than 24 months in the United States (Table 37-4; see also Table 37-1). The risk of death in a motor vehicle crash can be reduced by half with the use of age-appropriate child restraints. Emergency physicians should understand the various restraint types and recommendations for their use based on age, weight, and height. Every pediatric visit to the emergency department involves transportation to and from the emergency department and is an opportunity to counsel parents on the safe transport of their children.

### Acute Care

The acute care component of injury control involves trauma system planning, medical direction of out-of-hospital care, and providing systematized resuscitative care after the injury, whether it occurs close to or far from a trauma center. A crucial part of injury assessment is identification of local resources for management of the injured patient. Algorithms and agreements to transfer the patient to definitive care should be established to avoid secondary injury from delays in transfer or inappropriate care. Likewise, an environment with ready availability of trauma physician specialists should have clear protocols in place for use of those resources. Cost-effective mobilization of injury care resources dictates that in-hospital triage criteria be developed for the care of the injured patient to avoid unneeded overuse of trauma surgery teams.

Trauma systems can be created that recognize and complement the exigencies of budgetary, geographic, and political constraints that are specific to states or regions. Such flexibility is often impossible when a trauma system is based only on the locations of hospitals that seek trauma center verification or designation.

An inclusive trauma care system is one that comprises all acute care and rehabilitation facilities that treat injured patients...
and deals with the issues of community access, EMS dispatch and response, triage, transport and transfer protocols, training, communications, availability of definitive care and rehabilitation, and a data collection system. In an inclusive trauma care system, every injured patient (not just patients who live near trauma centers) is cared for by a part of the system. Every hospital has a role in an inclusive trauma system according to the services it is capable of offering, whether it is the expeditious transfer of patients, the treatment of patients without neurotrauma, or the definitive care provided at a trauma center. The system should be designed to monitor patient outcomes and system performance. The finding that level 1 trauma centers improve severe trauma patient outcomes by 25% is further evidence of the importance of an inclusive trauma care system.

Out-of-hospital emergency care is an integral part of injury control. EMS response, triage, and treatment are the first critical steps in injury control after an injury event has occurred. Triage protocols must be well established to avoid unnecessary delays in definitive care. EMS providers have a unique vantage point to help the trauma physician assess a patient’s risk factors for immediate injuries and the risk of injury recurrence. EMS providers can observe the environment for information about mechanism of injury. Accurately reporting vehicle damage and other environmental circumstances associated with the injury event elucidates important biomechanical risk factors. EMS providers have also become more involved in primary injury prevention through injury risk identification, documentation of injury data, and safety education programs.

Emergency Medicine Leadership: Advocacy of Public Policy

Passing and enforcing laws are more effective than education in effecting individual behavior change for increasing safety actions such as seat belt and helmet usage. Emergency physicians and other trauma physicians are well positioned to provide lawmakers with factual information coupled with the perspective of firsthand experience of the effects of injury. Effective prevention interventions and policies with documented cost savings are more likely to occur when sound, scientific studies are made available to policymakers. Most public health regulations and traffic safety laws are under the jurisdiction of state legislatures and city and county governments. These policymakers are generally much more accessible to physicians and in need of local expertise than are policymakers at the federal level. Emergency physicians need to accept an important advocacy role for reducing injuries and incorporate injury control as a professional activity.

Community education aimed at people not yet injured may be effective when provided by an emergency physician. Emergency physicians are in a leadership role to deliver the message to school systems, the local housing authority, law enforcement, community service organizations, and policymakers. Trauma physicians can be effective spokespersons for injury prevention through the news media, especially after a newsworthy injury event, and can reframe the event from one of personal blame and behavior failure to a broader biosocial issue that requires environmental and policy interventions.

Public policy also determines where resources are used in a community. Environmental modifications and elimination of hazards are effective but often expensive. In contrast to education and law enforcement, environmental modifications are passive countermeasures that do not require any action by people. Such modifications might be lengthening a “walk” signal at a busy intersection to reduce auto–pedestrian injuries, especially in the elderly; increasing lighting in areas where personal assaults occur; or changing a playground surface from hard-packed earth to wood mulch. The need for such modifications may be known only if the physician is alert to the circumstances by asking “How did this happen?” and documenting the location and circumstances of injuries seen in daily practice.

KEY CONCEPTS

- Injury is the second most costly disease to society and the most serious disease of young people.
- Through interdisciplinary research, a better understanding of the epidemiology and biomechanics of injury will lead to new control strategies. These strategies would complement advances in acute care and trauma systems, which improve care to the patient after the injury occurs.
- Emergency physicians can incorporate injury control techniques into daily practice through clinical prevention services.
- Increasingly, emergency physicians are leaders in addressing and preventing injuries and complex biosocial problems.

Head Injury

Michelle H. Biros and William G. Heegaard

PERSPECTIVE

Epidemiology

The devastating consequences of head injury have been recorded since ancient times. Early neurosurgical records were primarily observational, with very few suggestions for treatment (Fig. 38-1). Despite centuries of investigation and the development of new and better intensive care, we still have not discovered effective therapies that can be applied after the injury to reverse most pathologic aspects of traumatic brain injury (TBI).

Each year, an estimated 1.5 million people sustain head injury in the United States. Of these, 1.1 million undergo emergency evaluation, including approximately 500,000 children younger than age 14 years. Overall, 80% sustain minor head trauma (Glasgow Coma Scale [GCS] score = 14–15), 10% have moderate head injuries (GCS = 9–13), and 10% have severe head injuries (GCS ≤8). Almost 20% of all head-injured patients are hospitalized, and approximately 52,000 patients die each year from TBI.

The leading causes of head injury in the civilian population are falls (28%) and motor vehicle collisions. Traumatic brain injury due to blasts has been called the signature injury of the war in Iraq and Afghanistan: TBI of any severity is estimated to affect as many as 10 to 20% of war-time service members. Head injury is the leading cause of traumatic death in patients younger than 25 years and accounts for nearly one third of all trauma deaths. Head injury from child abuse is common and estimated to represent up to two thirds of cases in the 0- to 4-year-old age group. The Centers for Disease Control and Prevention estimates that there are at least 5.3 million Americans currently suffering from some degree of disability due to TBI. As veterans return to the United States, the numbers of patients suffering from the consequences of TBI are projected to increase markedly.

These facts confirm that TBI is a major public health problem. The emergency physician sees patients with head injuries of different clinical severity caused by a variety of mechanisms. External physical signs of head trauma only confirm that injury has occurred; they are not always present in the patient who has sustained serious underlying TBI. The ultimate survival and neurologic outcome of the head trauma patient depend on the extent of TBI occurring at the time of injury, alone or in combination with secondary systemic insults such as hypotension and hypoxia, which worsen the resulting neurochemical and neuroanatomic pathophysiology. Research aimed at reducing or preventing the neurological consequences of head trauma is ongoing, but currently the clinical outcome following TBI depends on the circumstances of injury and early clinical management aimed at reducing the occurrence of secondary brain insults. No effective intervention has been found to reverse the pathologic events initiated by the traumatic event.

PRINCIPLES OF DISEASE

Anatomy and Physiology

Scalp and Cranium

The scalp consists of five tissue layers. The dermis is the outermost layer and is among the thickest layers of skin on the body. The underlying subcutaneous tissue contains the hair follicles and the rich blood supply of the scalp. The large blood vessels of the scalp do not fully constrict if they are lacerated and can be the source of significant blood loss. The middle scalp layer is the galea, which is made of tough fascial tissue. It contains the occipitofrontalis and temporoparietalis muscles, which move the scalp backward and forward, elevate the eyebrows, and wrinkle the forehead. Under the galea is a loose areolar tissue layer. Because the areolar attachments to the rest of the scalp are loose, scalp avulsions frequently occur through this layer. This is also the site for development of subgaleal hematomas, which can become quite large because blood easily dissect through the loose areolar tissue. The deepest layer of the scalp, the pericranium, is firmly adhered to the skull.

The skull comprises the frontal, ethmoid, sphenoid, and occipital bones and two parietal and two temporal bones. The unique layered architecture of the bones of the skull enhances its strength. Each bone consists of solid inner and outer layers, separated by a layer of cancellous bone tissue (the diploe). In adults, the bones of the skull average between 2 and 6 mm in thickness; the bones in the temporal region are usually the thinnest of the skull. The cranial bones form a smooth outer surface of the skull, but within the cranial vault are many bone protrusions and ridges. Contrecoup injuries and contusions far from the site of head impact often occur as the accelerating brain strikes against these uneven bone surfaces.

The inner aspect of the skull is lined with the periosteal dura, which is a thick connective tissue layer that adheres closely to the bone surface. The inner meningeal layer of the dura is the outermost covering of the brain. This dural membrane reflects back on itself to make folds within the cranial...
space. These folds serve to protect and compartmentalize different components of the brain. The midline falx cerebri separates the two cerebral hemispheres from each other. The tentorium cerebelli partitions the cerebellum and brainstem from the cerebral hemispheres. The U-shaped free margin of this dural fold is important in the pathology of the transtentorial herniation syndromes that can complicate severe head injury. Within the margins of the dural reflections, the two dural layers separate to form large dural venous sinuses. Injury to the dural sinuses is associated with significant morbidity and mortality because of the potential for uncontrolled hemorrhage and the difficulty in repairing these structures.

The cranial vault is rigid and nonexpandable, with an average volume in adults of approximately 1900 mL. Cranial contents exit or enter the skull through many foramina. The largest, the foramen magnum, is the site of exit of the brain-stem and spinal cord from the cranium.

Brain and Cerebrospinal Fluid

The brain is a semisolid structure, which weighs approximately 1400 g (3 pounds) and occupies approximately 80% of the cranial vault. It is covered by three distinct membranes: the meningeal dura, the arachnoid layer, and the pia. The location of traumatic hematomas relative to these membranes defines the pathologic condition and determines the consequences of the injury.

The major divisions of the brain are the cerebrum, cerebellum, and brainstem. Each lobe of the cerebrum is the source of highly specific neurobehavior, and specific injury to each lobe can disrupt normal behavior patterns. The brain is suspended in the cerebrospinal fluid (CSF), which provides some buffering for the brain during trauma. CSF is produced by the choroid plexus, located primarily in the lateral ventricles of the brain. CSF passes from the ventricular system into the sub-arachnoid space that surrounds the brain and spinal cord. CSF provides a fluid pathway for delivery of substances to brain cells, elimination of the products of brain metabolism, and transport of peptide hormones and hormone-stimulating proteins from their site of production within the central nervous system (CNS) to their peripheral sites of action.

The normal pressure exerted by the CSF is 65 to 195 mm H2O or 5 to 15 mm Hg. Blood within the ventricles can obstruct the flow of CSF, causing a traumatic hydrocephalus. Brain injury and its complications can also alter the pH of CSF. Because the pH of CSF influences pulmonary drive and cerebral blood flow (CBF), any alteration can produce detrimental neurophysiologic consequences.

Cerebral Hemodynamics

Blood-Brain Barrier. The blood-brain barrier (BBB) maintains the microenvironment of the brain tissue. Extracellular ion and neurotransmitter concentrations are regulated by movement across this barrier. When the BBB is intact, the ability of neuroactive drugs to penetrate into the brain tissue usually depends on their lipid solubility. Post-traumatic cerebral edema and possibly the biomechanics of the injury itself can cause a prolonged disruption of the BBB for up to several hours after trauma. Prolonged disruption of the BBB contributes to the development of post-traumatic vasogenic cerebral edema.

The brain has an extremely high metabolic rate, using approximately 20% of the entire oxygen volume consumed by the body. To provide for its high metabolic demands, the brain requires approximately 15% of the total cardiac output. Optimal regional CBF is maintained by the ability of cerebral vessels to alter their diameter in response to changing physiologic conditions. Hypertension, alkalosis, and hypocarbia promote cerebral vasoconstriction; hypotension, acidosis, and hypercarbia cause cerebral vasodilation. In the normal brain, CBF is maintained at constant levels with a mean arterial pressure (MAP) of 60 to 150 mm Hg. This is referred to as autoregulation. Outside this range, the CBF varies linearly with MAP.

Cerebral vasoactivity is very sensitive to changes in systemic carbon dioxide and oxygen partial pressures (Pco2 and Po2, respectively). The response to changes in Pco2 is nearly linear between Pco2 values of 20 and 60 mm Hg. In this range, lowering Pco2 by as little as 1 mm Hg decreases the diameter of cerebral vessels by 2 or 3%, which corresponds to an overall change in CBF of 1.1 mL per 100 g of tissue per minute. The physiologic response of blood vessels to Pco2 is the rationale for the acute use of brief hyperventilation to control increased intracranial pressure (ICP) after head injury. As Pco2 decreases with hyperventilation, cerebral vasoconstriction occurs. As a result, the volume of blood per unit area of brain tissue decreases. This decrease (even if small) may buffer the effects of increasing edema or an expanding hematoma within the rigid cranial vault. The vasoconstriction produced by extreme changes in Pco2 (20 mm Hg or less) can be so pronounced that some areas of brain experience ischemia; subsequently, tissue hypoxia may occur. Therefore, hyperventilation must be controlled and monitored, with a goal of maintaining the Pco2 between 30 and 35 mm Hg and reserved for patients who are showing signs of acute herniation. Over 12 to 24 hours, injured vessels may lose their responsiveness to hyperventilation-induced hypocarbia and become vasodilated. Blood may then be shunted to the injured area, resulting in increased brain swelling and mass effect. Prolonged (i.e., beyond the acute resuscitation) or prophylactic hyperventilation is therefore not recommended as a treatment for increased ICP, and hyperventilation is not used for the routine management of head-injured patients with no signs of increased ICP.

The neurologic effects of hypcapnia are illustrated in Figure 38.2.
The cerebral vessels also respond to changes in Po₂. As Po₂ declines, cerebral vessels dilate to ensure adequate oxygen delivery to brain tissue. When brain injury has occurred, increased CBF in the presence of a disrupted BBB can promote the formation of vasogenic edema. Avoiding or reversing hypoxia is therefore an essential goal in the acute management of the head-injured patient. The responses of the cerebral vasculature to changing physiologic conditions protect the brain by increasing the delivery of oxygen to tissue, enhancing the removal of metabolic end products and allowing nearly instantaneous adjustments of regional blood flow to meet the changing metabolic demands.

Cerebral Perfusion Pressure. CBF also depends on cerebral perfusion pressure (CPP), which is the pressure gradient across the brain. The determinants of CPP are MAP and the resistance to CBF produced by mean systemic venous pressure and ICP. Because ICP is higher than mean systemic venous pressure, ICP effects predominate. Therefore, CPP is estimated as MAP minus ICP. CBF remains constant when CPP is 50 to 160 mm Hg. If CPP falls below 40 mm Hg, the autoregulation of CBF is lost, CBF declines, and the resultant tissue ischemia critically affects cerebral metabolism. It is essential to avoid or correct hypotension in the patient with multiple trauma who is also head injured so that the CPP can be maintained. Management must also be directed at reducing or preventing increased ICP to ensure adequate CPP to sustain cerebral metabolic needs.

Biomechanics of Head Trauma

Direct Injury. Direct impact head injury occurs when the head is struck by an object or its motion is arrested by another object. The resulting damage depends on the consistency, mass, surface area, and velocity of the object striking the head. Direct injury can also be caused by compression of the head. External signs of trauma are frequently noted at the site of application of the impact or compression force. The skull initially bends inward at the point of contact. If the force is sufficient, a skull fracture can occur. The cranium absorbs some of the applied energy, and some energy is transmitted to the brain by shock waves that travel distant to the site of impact or compression. These shock waves distort and disrupt intracranial contents and temporarily alter regional ICP as they propagate. In general, the more rapidly a force is applied, the greater the damage it causes. The extent of direct injury depends on the vasoelastic properties of the underlying region of brain tissue, the duration of the force applied, the magnitude of the force reaching the brain tissue, and the surface area of the brain that is affected by the application of the force. In cases of penetrating trauma, the mass, shape, direction, and speed of the penetrating object also affect the extent of direct injury.
Direct injury from compression of the head requires significant force because the architecture of the skull provides substantial resistance to deformation. In the clinical setting, compression injury is less common than other types of direct impact. With sufficient and prolonged application of compression force, the ability of the skull to absorb the force is overcome, and multiple linear skull fractures occur. Resulting fractures can be depressed if a high-energy rapid compression force is applied to a small area of the skull. Isolated direct impact injury is rare; direct impact usually sets the head in motion, resulting in simultaneous direct and indirect injury.

**Indirect Injury.** In indirect brain injury, the cranial contents are set into motion by forces other than the direct contact of the skull with another object. A common example is acceleration–deceleration injury, such as the shaken impact syndrome. No direct mechanical impact is sustained, but the cranial contents are set into vigorous motion. The brain moves within the skull, and bridging subdural vessels are strained. Subdural hematomas may result. Differential acceleration of the cranial contents occurs, depending on the physical characteristics of the brain region. As one brain region slides past another, shear and strain injuries are produced. This movement results in diffuse injuries, such as diffuse axonal injury or concussion. Additional injury occurs as the movement of the intracranial contents is abruptly arrested and the brain strikes the skull or a dural structure. Contrecoup contusions are an example of the injury produced in this manner. In penetrating injury, the traversal of the object produces pressure waves that can strike structures distal to the path of the missile.

### Brain Cellular Damage and Death

#### Primary and Secondary Brain Injuries

The acute clinical picture of the patient with TBI is dynamic and represents the sum of primary and secondary injury. Primary brain injury is mechanical irreversible damage that occurs at the time of head trauma and includes brain lacerations, hemorrhages, contusions, and tissue avulsions. On the microscopic level, primary injury causes permanent mechanical cellular disruption and microvascular injury. No specific intervention exists to repair or reverse primary brain injury; the only way to decrease brain injury is through public health interventions aimed at reducing the occurrence of head trauma.

The circumstances and extent of the primary injury are not the only contributors to the final neurologic outcome after head injury. The traumatic event also produces injury at the functional and anatomic cellular level, which begins soon after the impact and continues for several hours and even days after injury. Secondary brain injury results from intracellular and extracellular derangements that are probably initiated at the time of trauma by a massive depolarization of brain cells and subsequent ionic shifts. Animal studies have revealed a complicated series of neurochemical, neuroanatomic, and neurophysiologic reactions after head injury (Fig. 38-3). The cell has some compensatory mechanisms to protect itself from widespread damage, such as endogenous free radical scavengers and antioxidants. With significant trauma, however, these systems are quickly overwhelmed, and the functional and structural integrity of the cell is threatened. Human studies document similar changes. Studies suggest that abnormal genetic responses may play a role in response to injury, such as prompting apoptotic cell death. The relative importance and contribution of each adverse reaction to the final functional status of the damaged cell are uncertain, as are the rate and duration of each detrimental event. All currently used acute therapies for TBI are directed at reversing or preventing secondary injury. Experimental evidence for many investigational agents aimed at specific steps in the destructive processes suggests that some aspects of secondary brain injury may be reversed or modified. Multiple ongoing head injury trials have been performed with numerous investigational therapeutic interventions; to date, none have proved useful in the clinical setting.

#### Secondary Systemic Insults

The final neurologic outcome after head trauma is influenced by the extent and degree of secondary brain injury. In turn, the amount of secondary brain injury depends on certain pre-morbid and comorbid conditions, such as the age of the patient and trauma-related systemic events. A primary goal in the emergency care of the head-injured patient is prevention or reduction of systemic conditions that are known to worsen outcome after TBI.

Common secondary systemic insults in trauma patients include hypotension, hypoxia, and anemia and hyperpyrexia. Hypotension, defined as a systolic blood pressure less than 90 mm Hg, has been found to have negative impact on severe head injury outcome. Systemic hypotension reduces cerebral perfusion, thereby potentiating ischemia and infarction. The presence of hypotension nearly doubles the mortality from head injury and worsens the outcome of the patients who survive.

Hyperpyrexia (core body temperature >38.5 °C) is also correlated with worsened outcomes after TBI, and both its magnitude and its duration seem to contribute. The exact mechanism by which it causes damage is yet to be determined but likely involves stimulation of metabolism in injured areas of the brain, thus recruiting blood flow with a resultant increase in ICP.

Hypoxia, defined as a Po2 less than 60 mm Hg, probably occurs often in the head-injured patient. Causes include (1) transient or prolonged apnea caused by brainstem compression...
or injury after the traumatic event; (2) partial airway obstruction caused by blood, vomitus, or other debris in the airway of the traumatized patient; (3) injury to the chest wall that interferes with normal respiratory excursion; (4) pulmonary injury that reduces effective oxygenation; and (5) ineffective airway management, such as the inability to bag-valve-mask or intubate the patient in an effective or timely manner, respectively. The exact incidence of hypoxia in the head-injured patient is difficult to estimate because it is often unnoticed or undocumented in the out-of-hospital setting. When its occurrence is documented, the overall mortality from severe head injury may double or quadruple. Increased recognition of the potentially devastating consequences of hypoxia has led to more vigilance in the out-of-hospital and emergency setting.

Anemia caused by blood loss can be detrimental to the head-injured patient by reducing the oxygen-carrying capacity of the blood, thus reducing the amount of necessary substrate delivered to the injured brain tissue. When anemia (hematocrit <30%) occurs in patients with severe head injury, the mortality rate increases. Other potential reversible causes of systemic insult in head injury include hypercarbia, hyperthermia, coagulopathy, and seizures.

Pathophysiology

Increased Intracranial Pressure

ICP represents a balance of the pressures exerted by the contents of the cranial cavity. This relationship is explained by the Monro-Kellie doctrine. Because the craniospinal intradural space is almost nonexpandable, the sum of the volume of brain, CSF, and blood within the cranial cavity must remain constant. If the volume of any of these components increases, the volume of another must decrease to maintain a constant. If the volume of any of these components increases, the volume of another must decrease to maintain a constant. If the volume of any of these components increases, the volume of another must decrease to maintain a constant. If the volume of any of these components increases, the volume of another must decrease to maintain a constant. If the volume of any of these components increases, the volume of another must decrease to maintain a constant. If the volume of any of these components increases, the volume of another must decrease to maintain a constant. If the volume of any of these components increases, the volume of another must decrease to maintain a constant.

Increased ICP is defined as CSF pressure greater than 15 mm Hg (or 195 mm H2O) and is a frequent consequence of severe head injury. Initially, as ICP increases as a result of a traumatic mass lesion or edema formation, the CSF is displaced from the cranial vault to the spinal canal, offsetting the increased blood or brain volume. When this compensatory mechanism is overwhelmed, the elastic properties of the brain substance allow tissue compression to provide buffering for the increasing pressure. Depending on the location and the rate of expansion of the traumatic mass lesion and the rate of cerebral edema formation, the intracranial compensatory mechanisms can accommodate an increased volume of 50 to 100 mL. Beyond that, even small additional changes in intracranial volume relationships, such as those caused by vasodilation, CSF obstruction, or small areas of focal edema, cause a dramatic increase in ICP. If ICP increases to the point where CPP is compromised, vasoparalysis occurs and autoregulation is lost. The CBF then depends directly on the systemic MAP. With the loss of autoregulation, massive cerebral vasodilation occurs. Systemic pressure is transmitted to the capillaries, and the outpouring of fluids into the extravascular space can contribute to vasogenic edema and thus further increase ICP. If ICP rises to the level of the systemic arterial pressure, CBF ceases and brain death occurs.

Methods to reduce elevated ICP include hyperventilation, use of osmotic and diuretic agents, and CSF drainage. Uncontrollable increased ICP is defined as an ICP of 20 mm Hg or higher refractory to treatment. If ICP is not controlled, herniation syndromes can occur, resulting in brainstem compression and subsequent cardiorespiratory arrest. In the United States, the use of ICP monitoring and control has become standard in cases of moderate and severe TBI despite the lack of prospective controlled research showing clear efficacy as an individual patient treatment modality.

Brain Swelling and Cerebral Edema

Two primary types of brain swelling occur after head injury. Congestive brain swelling results from an increased intracranial blood volume. Hyperemia occurs early after trauma and can persist for the first few days after injury. It is especially common in children. The increased blood volume is most likely caused by vasodilation, which occurs as a compensatory mechanism to maintain optimal CBF in the presence of increased metabolic needs of the damaged brain tissue.

Cerebral edema is an increase in brain volume caused by an absolute increase in cerebral tissue water content. Diffuse cerebral edema may develop soon after head injury; however, its presence and extent do not always correlate with the severity of head injury. On computed tomography (CT) scans, diffuse edema is manifest as bilateral compression of the ventricles, loss of definition of the cortical sulci, or effacement of the basal cisterns (Fig. 38-4). Focal edema adjacent to traumatic mass lesions demonstrates decreased density on CT scans compared with normal tissue. CT can also detect a mass effect, caused by edema surrounding a traumatic lesion.

Both vasogenic and cytotoxic cerebral edema occur in the setting of trauma; the incidence and onset of each relative to the other depend on the nature of the injury. Vasogenic edema arises from transvascular leakage caused by mechanical failure of the tight endothelial junctions of the BBB. Vasogenic edema accumulates preferentially in white matter and can become widespread. It is frequently associated with focal conusions or hematomas. Vasogenic edema eventually resolves as edema fluid is reabsorbed into the vascular space or the ventricular system.

![Figure 38-4. Non-contrast-enhanced computed tomography scan showing diffuse cerebral edema. Loss of gray-white differentiation in brain parenchyma is present. Bilateral compression of the ventricles has occurred with loss of cortical sulci.](image-url)
Cytotoxic edema is an intracellular process that results from membrane pump failure. It is common after head injury and is frequently associated with post-traumatic ischemia and tissue hypoxia. Normal membrane pump activity depends on adequate CBF to ensure adequate substrate and oxygen delivery to brain tissue. If the CBF is reduced to 40% or less of baseline, cytotoxic edema begins to develop. If CBF drops to 25% of baseline, membrane pumps fail and cells begin to die. Congestive brain swelling can contribute to cytotoxic edema if it becomes severe enough to increase ICP and reduce CPP so that cerebral circulation cannot be maintained. Recent work suggests that cytotoxic cerebral edema is the predominant form of edema in patients who have experienced TBI.

Altered Levels of Consciousness

Consciousness is the state of awareness of the self and of the environment, and it requires intact functioning of the cerebral cortices and the reticular activating system (RAS) of the brainstem. An altered level of consciousness is the hallmark of brain insult from any cause and results from an interruption of the RAS or a global event that affects the cortices of both hemispheres.

A patient who has sustained TBI typically has an altered level of consciousness. Head trauma patients may be hypoxic from injury to respiratory centers or from concomitant pulmonary injury. Hypotension from other associated injuries can compromise CBF and affect consciousness. Global suppression may result from an intoxicant consumed before the injury, hypoglycemia, a post-traumatic seizure, or a postictal period following a seizure from any cause. With increasing ICP from brain swelling or an expanding mass lesion, brainstem compression and subsequent RAS compression can occur.

Patients with altered levels of consciousness require careful monitoring and observation. Reversible conditions that can alter mental status, such as hypoxia, hypotension, or hypoglycemia, should be corrected as they are identified.

Cushing’s Reflex

Progressive hypertension associated with bradycardia and diminished respiratory effort is a specific response to acute, potentially lethal increases in ICP. This response is called the Cushing reflex, or Cushing’s phenomenon, and its occurrence indicates that the ICP has reached life-threatening levels. The Cushing reflex can occur whenever ICP is increased, regardless of the cause. The full triad of hypertension, bradycardia, and respiratory irregularity is seen in only one third of cases of life-threatening increased ICP.

Cerebral Herniation

Cerebral herniation occurs when increasing cranial volume and ICP overwhelm the natural compensatory capacities of the CNS (Fig. 38-5). Increased ICP may be the result of post-traumatic brain swelling, edema formation, traumatic mass lesion expansion, or any combination of the three. When increasing ICP cannot be controlled, the intracranial contents shift and herniate through the cranial foramen. Herniation can occur within minutes or up to days after TBI. When the signs of herniation syndrome are present, however, mortality approaches 100% without rapid implementation of temporizing emergency measures and definitive neurosurgical therapy.

Uncal Herniation. The most common clinically significant traumatic herniation syndrome is uncal herniation, a form of transtentorial herniation. Uncal herniation is often associated with traumatic extra-axial hematomas in the lateral middle fossa or the temporal lobe. The classic signs and symptoms are caused by compression of the ipsilateral uncus of the temporal lobe on the U-shaped edge of the tentorium cerebelli as the brain is forced through the tentorial hiatus. As compression of the uncus begins, the third cranial nerve is compressed; anisocoria, ptosis, impaired extraocular movements, and a sluggish pupillary light reflex develop on the side ipsilateral to the expanding mass lesion. This phase may last for minutes to hours, depending on how rapidly the expanding lesion is changing. As the herniation progresses, compression of the ipsilateral oculomotor nerve eventually causes ipsilateral pupillary dilation and nonreactivity.

Initially in the uncal herniation process, the motor examination can be normal, but contralateral Babinski’s responses develop early. Babinski’s sign is dorsiflexion of the great toe and fanning of the other toes. Contralateral hemiparesis develops as the ipsilateral peduncle is compressed against the tentorium. With continued progression of the herniation, bilateral decerebrate posturing eventually occurs; decorticate posturing is not always seen with the uncal herniation syndrome. In up to 25% of patients, the contralateral cerebral peduncle is forced against the opposite edge of the tentorial hiatus. Hemiparesis is then detected ipsilateral to the dilated pupil and the mass lesion. This is termed Kernohan’s notch syndrome and causes false-localizing motor findings.

As uncal herniation progresses, direct brainstem compression causes additional alterations in the level of consciousness, respiratory pattern, and cardiovascular system. Mental status changes may initially be quite subtle, such as agitation, restlessness, or confusion, but soon lethargy occurs with progression to frank coma. The patient’s respiratory pattern may initially be normal, followed by sustained hyperventilation. With continued brainstem compression, an ataxic respiratory pattern develops. The patient’s hemodynamic status may change, with rapid fluctuations in blood pressure and cardiac conduction. Herniation that is uncontrolled progresses rapidly to brainstem failure, cardiovascular collapse, and death.

Central Transtentorial Herniation. The central transtentorial herniation syndrome is demonstrated by rostrocaudal neurologic deterioration caused by an expanding lesion at the vertex or the frontal or occipital pole of the brain. It is less common than uncal transtentorial herniation. Clinical deterioration occurs as bilateral central pressure is exerted on the brain from above. The initial clinical manifestation may be a subtle change in mental status or decreased level of consciousness, bilateral motor weakness, and pinpoint pupils (<2 mm). Light reflexes are still present but are often difficult to detect. Muscle tone is increased bilaterally, and bilateral Babinski’s signs may be present. As central herniation progresses, both pupils become midposition and lose light responsiveness. Respiratory patterns are affected and sustained hyperventilation may occur. Motor tone increases. Decorticate posturing is elicited by noxious stimuli. This progresses to bilateral decorticate and then spontaneous decerebration posturing. Respiratory patterns initially include yawns and sighs and progress to sustained tachypnea, followed by shallow slow and irregular breaths immediately before respiratory arrest.

Cerebellotonsillar Herniation. Cerebellotonsillar herniation occurs when the cerebellar tonsils herniate downward through the foramen magnum. This is usually caused by a cerebellar mass or a large central vertex mass causing the rapid displacement of the entire brainstem. Clinically, patients demonstrate sudden respiratory and cardiovascular collapse as the medulla is impinged. Pinpoint pupils are noted. Flaccid quadriplegia is the most common motor presentation because of bilateral compression of the corticospinal tracts. Mortality from cerebellar herniation approaches 70%. Upward Transtentorial Herniation. Upward transtentorial herniation occasionally occurs as a result of an expanding posterior fossa lesion. Level of consciousness declines rapidly. These patients may have pinpoint pupils from compression of the pons. Downward conjugate gaze is accompanied by the absence of vertical eye movements.

CLINICAL FEATURES AND DIAGNOSTIC STRATEGIES

History

Details regarding the mechanism of injury should be solicited from witnesses or the victim to determine whether the head-injured patient is at high risk for intracranial injury. The patient’s condition before trauma may give clues to important, otherwise unsuspected, comorbid factors such as preexisting coagulopathy (i.e., hemophilia). Past medical history, medications (particularly anticoagulants), recent drug or alcohol use, and complaints immediately preceding the traumatic event should be determined.

The patient’s current level of consciousness, as well as that immediately before and after the injury and at the arrival of first responders, should be determined. Witnessed posttraumatic seizures or apnea should be reported. If the patient is now awake but was unconscious at some point, it should be determined if the patient has returned to baseline mental status.

Acute Neurologic Examination

General

The goals of the acute neurologic assessment of head-injured patients include detection of life-threatening injuries and identification of neurologic changes in the immediate posttrauma period. An awake, stable patient can undergo a relatively complete neurologic examination. In other patients, an efficient neurologic examination in the emergency setting includes evaluation of mental status, GCS score, pupillary size and responsiveness, and motor strength and symmetry. An accurate neurologic assessment in the immediate posttrauma period serves as a basis for comparison in subsequent examinations. If a formal GCS measure is not possible or is difficult because of comorbid confounders, the patient’s mental status should be described in as much detail as possible. Declining mental status after head trauma suggests increasing ICP from an expanding mass lesion or worsening cerebral edema, which may rapidly become life threatening.

Glasgow Coma Scale

The GCS is an objective method of following the patient’s neurologic status (Table 38-1). The GCS assesses a patient’s best eye, verbal, and motor responsiveness. It was developed for the clinical evaluation of head trauma patients at 6 hours after trauma, and all initial validation studies investigated its application at this time. It was designed for assessment of patients with isolated head trauma who were hemodynamically stable and adequately oxygenated. The GCS is only one aspect of the neurologic examination (i.e., the motor score reflects best limb movement, and it cannot detect subtle changes in mental status). However, because of its interrater

CNS, central nervous system.

reliability, reliance on objective clinical data, and ease of application, the GCS has become a standard acute measure of neurologic function in patients with altered mental status from any cause, including head trauma.

The acute application (<6 hours) of the GCS in head-injured patients has limitations. Hypoxia, hypotension, and intoxication can falsely lower the initial GCS. Intubation lowers the patient’s GCS by automatically assigning a score of 1 for verbal response, regardless of the actual contribution of head injury to the clinical examination. Periorbital edema from direct eye trauma may make assessment of spontaneous eye opening difficult. Extremity fractures or occult spinal cord injuries may interfere with the motor examination. Children and non-English-speaking patients are difficult to assess with the GCS. The GCS may miss subtle mental status changes and does not assess brainstem reflexes or pupillary reflexes. Decisions regarding continued resuscitation of severely head-injured patients should not be based on the initial GCS because of these limitations. Patients must be fully resuscitated, with evacuation of all surgical lesions, must remain hemodynamically stable, and must not be intoxicated before the GCS can be used to predict their prognosis.

Pupillary Examination

An evaluation of the patient’s pupil size and responsiveness must be done early in the initial assessment of the head-injured patient. Pupillary asymmetry, the loss of the light reflex, or a dilated pupil suggests herniation syndrome. Traumatic mydriasis, resulting from direct injury to the eye and periorbital structures, may confuse the assessment of the pupillary responsiveness.

Motor Examination: Posturing

The patient’s acute motor examination assesses for strength and symmetry. Paralysis obscures involuntary reflexes; attempts should be made to assess the motor exam before paralytic agents are given. Hemiparesis contralateral to a fixed and dilated pupil suggests herniation syndrome. A false-localizing motor examination can be caused by contralateral cerebral parenchymal injury occurring simultaneously with the expanding mass lesion or by Kernohan’s notch syndrome (compression of the contralateral cerebral peduncle). False-localizing signs for the motor examination can also be caused by occult extremity trauma, spinal cord, or nerve root injury that makes the examination painful or difficult. If the patient is not cooperative or is comatose, motor movement should be elicited by application of noxious stimuli. Any movement should be recorded. Voluntary purposeful movement must be distinguished from abnormal motor posturing. Decorticate posturing is abnormal flexion of the upper extremity and extension of the lower extremity. The arm, wrist, and elbow slowly flex, and the arm is adducted. The leg extends and internally rotates, with plantar flexion of the foot. Decorticate posturing implies injury above the midbrain. Decerebrate posturing is the result of a more caudal injury and therefore is associated with a worse prognosis. The arms extend abnormally and become adducted. The wrist and fingers are flexed, and the entire arm is internally rotated at the shoulder. The neck undergoes abnormal extension, and the teeth may become clenched. The leg is internally rotated and extended, and the feet and toes are plantar flexed.

Brainstem Function

In the acute setting, brainstem activity is assessed by the patient’s respiratory pattern, pupillary size, and eye movements. The oculocephalic response (doll’s eyes maneuver) tests the integrity of the pontine gaze centers. This response cannot be tested until cervical spine fractures have been ruled out. The oculovestibular response (cold water calorics) also assesses the brainstem. Comatose patients no longer demonstrate nystagmus when cold water is placed in the ear canal; the only response is tonic deviation of the eyes toward the instilled cold water. This response is dampened by cerumen or blood in the patient’s ear canal, and the tympanic membrane must be intact to perform this test.

In the severely head-injured patient, the cranial nerve (CN) examination is often limited to the pupillary responses (CN III), gag reflex (CNs IX and X), and corneal reflex (CNs V and VII). Facial symmetry (CN VII) can sometimes be assessed if the patient grimaces with noxious stimuli. In patients who are awake and can cooperate, a formal CN examination should be performed.

Deep Tendon Reflexes and Pathologic Reflexes

Tendon reflexes should be tested for symmetry. An extensor plantar reflex (Babinski’s sign) is nonspecific and can be caused by injury anywhere along the corticospinal tract. Rectal sphincter tone and anal reflexes should be determined to assess for spinal cord integrity.
OUT-OF-HOSPITAL CARE

The goals of the out-of-hospital management of the head-injured patient are necessary airway interventions to prevent hypoxia and establishing intravenous (IV) access to treat trauma-related hypotension. An accurate neurologic assessment provides a means to determine the subsequent effectiveness of treatment and should focus on the GCS, pupillary responsiveness and size, level of consciousness, and motor strength and symmetry.

Head trauma can produce profound effects on the cardiovascular system if compression of the brainstem and medulla occurs. Any cardiac dysrhythmia can occur and produce cardiac instability. All head-injured patients should be placed on a cardiac monitor during transport from the accident scene.

The secondary survey of the head-injured patient should include a search for external signs of head trauma. Scalp lacerations may bleed a large volume into a bulky dressing. A less bulky dressing should be used with firm constant manual pressure applied to avoid excessive blood loss. Many severely head-injured patients are initially combative or agitated. Transporting an agitated patient who is fighting against physical restraints may exacerbate physical injury, cause an increase in ICP, and interfere with appropriate stabilization and management. It may be necessary to use out-of-hospital sedation or neuromuscular blockade for control. The use of sedatives or neuromuscular blockade may influence the initial emergency department evaluation of the neurotrauma patient. Therefore, the risks and benefits of this acute intervention must be carefully considered and decisions made on a case-by-case basis. Out-of-hospital protocols allowing the use of sedative agents for selected agitated head-injured patients should be established. Currently used agents include lorazepam (Ativan), diazepam (Valium), midazolam (Versed), and certain butyrophenones (i.e., haloperidol, droperidol, and triparanol).

Severe head injury is the most common reason for helicopter transfers in trauma care. Although the decision to transport by helicopter should be made on a case-by-case basis, considerations for helicopter use from an accident scene include a longer extrication time, ground transport of longer than 30 minutes to an appropriate emergency department and trauma care facility, two or more severely injured patients at a scene, and assistance in performing expedient lifesaving procedures, especially airway management.

Controversy exists regarding the benefits of out-of-hospital intubations in patients with severe and moderate head injuries. It is unclear if field intubations truly improve neurologic outcome or survival. Unsuccessful attempts at field intubations may add to out-of-hospital time and increase the risk for aspiration or hypoxia.

In 1997, Winchell and Hoyt showed that patients who had sustained severe head injuries and who were intubated in the out-of-hospital setting had an improved survival compared with those who were not intubated. Since that time, others have challenged this finding. In the San Diego paramedic rapid sequence intubation (RSI) trial, Davis and colleagues found an increase in mortality and morbidity in patients who sustained severe head injuries and underwent out-of-hospital RSI compared to matched historical controls. Potential explanations included frequent hypoxic episodes with associated bradycardia, unintentional hyperventilation, and prolonged scene times for those undergoing out-of-hospital RSI. Wang and colleagues found a fourfold increase in mortality among patients who sustained severe TBI and received ground ambulance intubation compared with emergency department intubation. Flight clinician out-of-hospital intubation was associated

Other Examination Findings

The head and neck should be carefully examined for external signs of trauma that may have also produced underlying TBI. A scalp laceration, contusion, abrasion, or avulsion may overlie a depressed skull fracture. Basilar skull fractures are usually diagnosed by the clinical examination (Box 38-1). Although not always related to severe brain injury, their presence implies that a significant impact force was sustained during head trauma. Carotid artery dissections caused by a hyperflexion-extension neck injury can occasionally be detected by auscultation of a carotid bruit. In these patients, a careful neurologic examination should assess for subtle asymmetry between the carotid arteries. The percentage of concurrent cervical spine injury in patients with severe head trauma may be as high as 10.2%. Often, other spinal regions are also injured.

MANAGEMENT

Severe Traumatic Brain Injury

The neurosurgical literature defines severe head injury as TBI manifested by a postresuscitation GCS of 8 or less within 48 hours. In the emergency setting, however, this definition is not practical because the outcome for the patient beyond the initial resuscitation is not known. Most emergency medicine research defines severe head injury by a GCS score of 8 or less at the acute presentation after injury. The presence of any intracranial contusion, hematoma, or laceration is also considered severe injury (Fig. 38-5).

Approximately 10% of all head-injured patients who reach the emergency department alive have severe head trauma. The clinical prognostic indicators in the acute setting are initial motor activity, pupillary responsiveness, the patient’s age and premorbid condition, and the occurrence of secondary systemic insult during the acute period. Up to 25% of these patients have lesions requiring neurosurgical evacuation. The prognosis cannot be reliably predicted by the initial GCS or initial CT scan.

The overall mortality in severe head trauma approaches 60%. Mortality for children is lower. For nonsurvivors of head injury who reach the hospital alive, the average time to death is 2 days after trauma. Adult survivors of severe head trauma are usually severely disabled; currently, only 7% have moderate disability or a good outcome. Children older than 2 years who survive a severe closed-head injury have a better outcome than adults.
with decreased mortality and improved neurologic outcome, likely due to the higher airway management training requirements of air medical programs. These studies are somewhat limited by lack of generalizability\textsuperscript{30-33} (i.e., most emergency medical service systems do not have RSI capabilities) or by the use of nonvalidated outcome measures of neurologic function.\textsuperscript{30} Out-of-hospital intubation carries the following risks: frequent hypoxic episodes during intubation attempts with or without concurrent bradycardia; unintentional hyperventilation of intubated patients; prolonged scene times because of the time demands associated with the intubation process; and persistent hypotension, likely from other injuries that go unattended while the airway management occurs. However, hypoxia must be avoided in head-injured patients, and out-of-hospital airway protocols must balance the risks of emergency intubation in an uncontrolled setting with the need to secure an airway at risk.

The key to a successful out-of-hospital RSI program involves well-trained clinicians with specific RSI protocols, involved medical control, frequent continuing education, and consistent quality assurance/improvement. Fakhry and colleagues\textsuperscript{34} reported that their helicopter clinicians had a 96.6% RSI success rate with few complications and no esophageal intubations.

**Emergency Department (Fig. 38-6)**

**Airway.** Rapid sequence intubation is an effective and the preferred method for securing the airway in combat or agitated patients. If possible, a brief neurologic examination should be performed if the patient is given any sedative or neuromuscular blocking agents. In general, the agents used for RSI in the head-injured patient are the same as those used for other patients, although attention must be given to the increased ICP that can potentially occur with any physical stimulation of the respiratory tract. Lidocaine (1.5–2 mg/kg IV push) may attenuate the cough reflex, hypertensive response, and increased ICP associated with intubation, although this is vigorously debated.\textsuperscript{33,36} If succinylcholine is used, premedication with a subparalytic dose of a nondepolarizing agent can be considered if time permits because fasciculations produced by succinylcholine may increase ICP. The degree of ICP elevation and its clinical significance are unclear, however, and must be balanced against the need for rapidly establishing an airway. Etomidate (0.3 mg/kg IV), a short-acting sedative-hypnotic agent, has beneficial effects on ICP by reducing CBF and metabolism.\textsuperscript{37} In addition, etomidate has minimal adverse effects on blood pressure and cardiac output and fewer respiratory depressant effects than other agents.

**Hypotension.** Hypotension is rarely caused by head injury except as a terminal event. If hypotension is detected at any time in the emergent management of a head-injured patient, a cause other than the head injury should be sought. Some important exceptions occur. Profound blood loss from scalp lacerations can cause hypovolemic hypotension. In small children, hemorrhage into an epidural or subgaleal hematoma can produce profound hypovolemic shock. In the presence of a concomitant high spinal cord injury, neurogenic hypotension may occur. This is rare and usually the cord injury is apparent on physical examination. In less obvious cases, neurogenic hypotension can be differentiated from hypovolemic hypotension by its nonresponsiveness to fluid administration and by the presence of inappropriate bradycardia in the face of hypotension in neurogenic shock.

Systemic hypotension cannot be tolerated in the head-injured patient without profound worsening of neurologic outcome; fluids or blood transfusion should therefore be delivered to maintain a systolic blood pressure of at least 90 mm Hg.\textsuperscript{19} The delivery of large amounts of fluid to severely head-injured patients who are hypotensive from other injuries does not produce clinically significant increases in ICP; fluids should never be withheld in the head trauma patient with hypovolemic hypotension for fear of increasing cerebral edema and ICP. Hypotension may interfere with the accurate neurologic assessment of the brain-injured patient. Often, when blood pressure is restored, an improved neurologic status is observed.

Traditionally, normal saline or lactated Ringer’s solution has been used for resuscitation of trauma patients with hypovolemic hypotension. Although it is not yet included in practice
guidelines on the management of head-injured patients, some researchers suggest that fluid resuscitation with hypertonic saline rather than normal saline may improve neurologic outcome after TBI. As many as 60% of patients with severe head injury are victims of multiple trauma. The dramatic presentation of the head injury should not distract the clinician from a thorough search for other life threats.

The emergency department neurologic assessment should be compared with the initial out-of-hospital examination, focusing on evidence of neurologic deterioration or signs of increasing ICP. If the patient is deteriorating or has signs of increased ICP, active intervention must be initiated in the emergency department.

**Hyperventilation.** Acute hyperventilation is a life-saving intervention that can prevent or delay herniation in the patient with severe TBI. The goal is to reduce the Pco2, to the range of 30 to 35 mm Hg. Hyperventilation will reduce ICP by causing cerebral vasoconstriction; the onset of effect is within 30 seconds and probably peaks within 8 minutes after the Pco2 drops to the desired range. In most patients, hyperventilation lowers the ICP by 25%; if the patient does not rapidly respond, the prognosis for survival is generally poor.

Prolonged hyperventilation is not recommended because it may cause profound vasoconstriction and ischemia. This vasoconstriction worsens cerebral blood flow that is already severely compromised during the first 24 hours after TBI. Hyperventilation should be viewed as a short-term lifesaving intervention and should be used only when a patient experiences an acute neurologic decline or demonstrates signs consistent with herniation.

**Osmotic Agents.** Additional therapy for increased ICP includes the use of osmotic diuretics, such as mannitol and hypertonic saline. With deepening coma, pupil inequality, or other deterioration of the neurologic examination, osmotic agents may be lifesaving.

Mannitol is the mainstay for control of elevated ICP acute severe TBI. The Brain Trauma Foundation and the European Brain Injury Consortium recommend mannitol as the osmotic drug of choice. However, little comparative data exist on mannitol and other ICP-lowering medications. A Cochrane database review concluded that mannitol may have a small beneficial effect compared to pentobarbital. ICP-directed therapy based on neurologic signs may also be beneficial. However, one study indicates that mannitol may be detrimental compared to hypertonic saline. Further research is needed on optimal osmotic therapy in severe head trauma.

Mannitol (0.25–1 g/kg) can effectively reduce cerebral edema by producing an osmotic gradient that prevents the movement of water from the vascular space into the cells during membrane pump failure and draws tissue water into the vascular space. This reduces brain volume and provides increased space for an expanding hematoma or brain swelling. The osmotic effects of mannitol occur within minutes and peak approximately 60 minutes after bolus administration. The ICP-lowering effects of a single bolus may last for 6 to 8 hours. Mannitol has many other neuroprotective properties. It is an effective volume expander in the presence of hypovolemic hypotension and therefore may maintain systemic blood pressure required for adequate cerebral perfusion. It also promotes CBV by reducing blood viscosity and microcirculatory resistance. It is an effective free radical scavenger, reducing the concentration of oxygen free radicals that may promote cell membrane lipid peroxidation. However, mannitol can produce renal failure or hypotension if given in large doses. It may also induce a paradoxical effect of increased bleeding into a traumatic lesion by decompressing the tamponade effect of a hematoma. Because of these and other potential problems, the use of mannitol should be reserved for head-injured patients with evidence of increasing ICP and neurologic deterioration.

Hypertonic saline (HTS) has been used for severe TBI since 1919. Preclinical studies have demonstrated that HTS can significantly reduce ICP; however, fewer than 300 patients have been enrolled in all clinical trials of HTS. The interpretation of these clinical studies is complicated by variation in protocols, HTS concentration, and administration. Few studies have been prospective, randomized, and controlled. Potential adverse events associated with HTS include renal failure, central pontine myelinolysis, and rebound ICP elevation.

Encouraging clinical data are available on hospitalized pediatric TBI patients treated with a continuous infusion of 3% normal saline for control of intracranial hypertension. The clinical studies using HTS for acute resuscitation of severe TBI are conflicting. Using a post hoc analysis of adult trauma data, Vassar and colleagues and Wade and colleagues showed beneficial effects of HTS on patients with severe TBI. However, Cooper and colleagues found no benefit for out-of-hospital use of HTS in reducing elevated ICP and improving CPP compared to lactated Ringer’s in hypotensive patients who had a head injury. Morbidity and mortality outcome data were equal in both groups. In summary, clinical effectiveness data on the use of HTS in head-injured adults for acute treatment of increased ICP are inconclusive, but research on this topic is ongoing.

**Barbiturates.** Barbiturate therapy is occasionally used in severely head-injured patients to reduce cerebral metabolic demands of the injured brain tissue. Barbiturates also affect vascular tone and inhibit free radical-mediated cell membrane lipid peroxidation. The effects of barbiturates are delayed relative to other acute interventions for reducing ICP; therefore, they are rarely initiated in the emergency department. If other methods of reducing ICP have been unsuccessful, barbiturates may be added in the hemodynamically stable patient. Pentobarbital is the barbiturate most often used.

**Steroids.** Despite their popularity in the past, there is no benefit to giving steroids in head-injured patients. They do not lower ICP, and high-dose methylprednisolone in moderate and severe TBI is associated with increased mortality.

**Hypothermia.** Although hypothermia remains a significant area of research and promise for severe and moderate TBI patients, the available scientific evidence does not support improved mortality or morbidity with prophylactic hypothermia in adult patients. In a meta-analysis performed by the Brain Trauma Foundation, duration of hypothermic treatment for more than 48 hours was associated with a reduction in mortality. This finding is significantly limited due to small sample sizes.

**Cranial Decompression.** Patients with signs of herniation who have not responded to other means of ICP reduction and who are rapidly deteriorating in the emergency department should be considered for placement of emergency burr holes. Emergency trephination has been described for centuries (Fig. 38-7). It is a blind invasive procedure, and the chances of localizing the expanding lesions are uncertain. In carefully considered patients, however, emergency cranial decompression may temporarily reverse or arrest the herniation syndrome, providing the time needed to prepare the patient for formal craniotomy.

Most patients who have been unconscious since an accident occurred—with erratic or absent respiratory effort, bilateral fixed and dilated pupils, no spontaneous eye movements, and decerebrate posturing—have sustained diffuse massive brain injury with no focal lesion amenable to emergency decompression. These patients probably do not benefit from emergent
Indications for Acute Seizure Prophylaxis in Severe Head Trauma

burr holes. Instead, these patients should undergo rapid CT scanning or formal surgical decompression.

Seizure Prophylaxis. Up to 12% of all patients who sustain blunt head trauma and 50% of those with penetrating head injury develop early post-traumatic seizures. Although the occurrence of seizures in the immediate posttrauma period has no predictive value for future epilepsy, early seizures can cause hypoxia, hypercarbia, release of excitatory neurotransmitters, and increased ICP, which can worsen secondary brain injury. Constantly firing neurons are soon depleted of their energy sources, and in the head trauma patient with compromised cerebral metabolism, uncontrolled seizures exacerbate the neurologic deficit.44

Box 38-2 lists accepted indications for early anticonvulsant therapy after head trauma. If the patient is actively seizing, benzodiazepines are administered as effective, rapid-acting first-line anticonvulsants. Lorazepam (0.05–0.15 mg/kg IV over 2–5 minutes up to a total of 4 mg) has been found to be most effective at aborting status epilepticus.30 Diazepam (0.1 mg/kg, up to 5 mg IV, every 10 minutes up to a total of 20 mg) is an alternative. For long-term anticonvulsant activity, phenytoin (18–20 mg/kg IV) or fosphenytoin (15–18 phenytoin equivalents/kg) IV or IM can be given. Fosphenytoin has the advantages of rapid administration, a smaller volume of fluid for the dose delivered, and less hypotension than phenytoin, although its cost is much higher. In a Cochrane review, the use of antiepileptic drugs reduced the risk of early seizures by 66%.31 Early seizure prophylaxis does not prevent late post-traumatic seizures; the goal is to prevent additional insult to the damaged brain.32,33

If the patient has been paralyzed to facilitate management, clinical manifestations of generalized seizures are obscured. Therefore, all paralyzed head-injured patients should have prophylactic anticonvulsant therapy in the acute phase. Continuous electroencephalographic monitoring is necessary for the ongoing assessment of seizure activity in paralyzed patients and, if available, should be initiated in the emergency department or the intensive care unit.

Antibiotic Prophylaxis. Infection may occur as a complication of penetrating head injury, open skull fractures, and complicated scalp lacerations. Prophylactic antibiotics may be used in these circumstances but are not recommended in patients with otorrhea or rhinorrhea from a basilar skull fracture.44

Recombinant factor VIIa (rFVIIa) is a hemostatic agent that was originally developed to treat bleeding in hemophiliacs. Considerable interest has arisen regarding its potential use in intracerebral hemorrhage.55,56 A single, appropriate dose of rFVIIa for a 70-kg individual can exceed $4500.56 Experience from the Iraq war has produced conflicting results regarding its benefits in traumatic intracranial hemorrhage. Use of rFVIIa for traumatic head bleeds should be individualized and made in concert with an institution’s treatment protocol.

Ancillary Evaluation

Laboratory Tests. The acute management of the severely head-injured patient is directed by physical examination and diagnostic imaging. Ancillary laboratory tests that may provide useful information in the subsequent management of the patient include a urine toxicology screen, blood alcohol level, complete blood count, electrolytes, glucose, and coagulation studies.

Neuroimaging. The advantages and indications for neuroimaging techniques in the acute evaluation of head injury are listed in Table 38-2. In the acute phase, the most useful imaging technique is a non-contrast-enhanced head CT scan. This scan delineates acute intra-axial and extra-axial bleeding, subarachnoid blood, cerebral swelling, ischemic infarction caused by hypoxia after trauma, evidence of increased ICP, and pneumocephalus. Emergency management decisions are strongly influenced by these acute CT scan findings. The bone windows of the CT scan can detect skull fractures (including basilar fractures); plain skull radiographs are not necessary in patients who undergo CT scanning.

Magnetic resonance imaging (MRI) is better than CT in detecting post-traumatic ischemic infarctions, subacute non-hemorrhagic lesions and contusions, axonal shear injury, and lesions in the brainstem or posterior fossa. Monitoring and managing patients in the MRI suite can be very difficult, especially in severe TBI patients who have other life-threatening injuries. MRI is not recommended as the first-line imaging modality for severe or moderate head injury.

Disposition Consultation. All patients with severe head trauma require an imaging modality to determine the extent and nature of the brain injury and the necessity of neurosurgical intervention.
Neurosurgical consultation should be obtained as soon as possible to help direct the patient’s subsequent management.

**Transfer.** Severe head-injured patients require admission to an institution capable of intensive neurosurgical care and acute neurosurgical intervention. If this is not available at the receiving hospital, the patient should be transferred to an appropriate institution by the most expedient transport method available.

**Priority Management.** The hemodynamically unstable patient with multiple trauma that includes head injury presents difficult emergency management decisions. The emergency physician must decide on the sequence that best addresses the most life-threatening pathologic conditions while still preventing morbidity and mortality from other serious injury. If the patient requires immediate surgical intervention for a life-threatening chest or abdominal injury, complete evaluation of the head injury may be curtailed. Moreover, these patients are anesthetized for surgery, and any neurologic deterioration is not detected. Some patients may be too unstable to obtain an abbreviated head CT scan before emergent surgical intervention for other life threats. In this circumstance, early neurosurgical and general surgical consultation should be coordinated by the emergency physician. Intraoperative ventriculostomies or bilateral trephinations may provide some temporary protection from increasing ICP while the patient undergoes surgical correction of the life-threatening injury. A CT scan can be performed after the primary life threats have been corrected.

CT, computed tomography.

Clinical Features and Acute Management

A wide variety of clinical presentations occur with moderate head injury. Patients often have experienced a change in consciousness at the time of injury, a progressive headache, post-traumatic seizures, vomiting, and post-traumatic amnesia. On emergency department presentation, patients are often confused or somnolent, but most can still follow commands. Focal neurologic deficits may be present. Many patients with moderate head trauma have concurrent serious facial injuries that may interfere with attempts at securing their airway. Other systemic trauma must also be ruled out.

An important clinical scenario in the spectrum of moderate head injury is that of the “talk and deteriorate” patient. These patients have a GCS score of 13 or greater on presentation but deteriorate to a status of severe head injury (GCS ≤8) within 48 hours. Although this description can include patients with minor head trauma, most patients who talk and deteriorate present with GCS scores suggesting moderate head trauma. When the syndrome was first described by Reilly more than 30 years ago, the incidence of death in head-injured patients who presented talking was estimated to be as high as 38%. However, CT scans were not readily available at that time, and the GCS was not in widespread use. With the current availability of early CT scanning, as well as rapid transport via emergency medical service, injuries are detected earlier, and the incidence of talk and deteriorate is now estimated to be 2.5 to 12%. In early descriptions of talk and deteriorate, most patients were found to have sustained subdural or epig.
dural hematomas. More recently, an equal number are found to have contusions with subsequent edema.\textsuperscript{57,61} Patients who talk and deteriorate are generally elders with higher injury severity scores.\textsuperscript{57,62} In addition, anticoagulation puts patients at increased risk.

Successful management of moderately head-injured patients involves close clinical observation for changing mental status or focal neurologic findings, early CT scanning, and aggressive neurosurgical intervention. When no neurosurgeon is available and the patient develops symptoms consistent with herniation syndrome not reversed by acute hyperventilation and mannitol, emergency department trephination and hematoma evacuation of any amenable lesion should be considered.

Because of the varied presentation of patients with moderate head trauma, the initial examination alone cannot accurately predict who will have surgically correctable intracranial lesions. Approximately 40\% of moderately head-injured patients have an abnormal CT scan, and 10\% lapse into coma.\textsuperscript{63} A CT scan is essential in patients with moderate head trauma to avoid delayed diagnosis of traumatic mass lesions or diffuse injury. This is especially true for elders or patients on anticoagulation therapy.\textsuperscript{54,65} Skull radiographs may be useful if the patient has sustained a depressed skull fracture or a penetrating injury but are otherwise rarely helpful.

**Disposition**

All patients with moderate head injury should be admitted for observation, even with an initial apparently normal CT scan. Ninety percent of patients improve over the first few days after injury.\textsuperscript{54,63} Frequent neurologic checks should be initiated, and a repeated CT scan is indicated if the patient’s condition deteriorates or fails to improve over the first 48 hours after trauma.

**Complications**

The overall mortality of patients with isolated moderate TBI is approximately 20\%, but the morbidity is substantial. Most moderate TBI patients remain symptomatic for extended periods after head injury. At 3 months after trauma, up to 70\% are unable to return to work, 90\% have memory difficulties, and more than 90\% complain of persistent headaches.\textsuperscript{63,66} Almost 50\% are left with a long-term disability that interferes with their previous daily activities. In patients with persistent symptoms of headache, confusion, or memory difficulties, delayed MRI may define lesions in the regions related to cognition that cannot be seen on CT. Although not useful in the acute setting, MRI has prognostic value during subsequent care and assists in directing the future rehabilitation of these patients.

**Minor Head Trauma**

Minor TBI is a temporary and brief interruption of neurologic function after head trauma, which may involve a loss of consciousness. The neuropathology involved in producing signs and symptoms of minor TBI may remain at the neurobiochemical level, without damage to the microstructure.\textsuperscript{67} Heightened ionic flux, surges in levels of glutamate transmitters, disruption of enzymatic pathways, and accumulation of lactate and nitric oxide have been reported in brain tissue after experimental minor TBI.\textsuperscript{14} Axonal stretching or twisting that may occur with some mechanisms producing minor TBI promote glutamine-induced neurotoxic cascades that may lead to the axonal damage typically described as diffuse axonal injury.\textsuperscript{68}

Traditionally, minor TBI was defined as injury producing a GCS score of 13 to 15. However, because many patients with a GCS of 13 have outcomes more consistent with moderate TBI, many authorities now classify minor TBI as that producing a GCS score of 14 or 15.\textsuperscript{68} In fact, the GCS is not sensitive enough to be of prognostic usefulness in minor TBI; a perfect score of 15 in the emergency department does not take into account the level of alertness or neurologic status immediately after trauma or the presence or absence of focal neurologic injury.\textsuperscript{68}

From a practical standpoint, minor TBI is a clinical diagnosis. The diagnosis requires a credible mechanism of injury. In civilian life, most mechanisms that do not involve direct craniofacial impact cannot produce minor TBI. For example, belted drivers in low-velocity rear-end impact motor vehicle crashes are not subjected to high enough acceleration-deceleration or rotary forces to the head to reach the force threshold needed to produce cerebral injury unless there is also direct impact to the head against a stationary object.\textsuperscript{69} It is therefore unlikely that a patient with a whiplash or “jolt” injury would also have minor TBI. Collision sports-related minor TBI can be caused by acceleration-deceleration. It is not known if the forces generated in blast injuries in wounded service personnel are large enough to cause minor TBI without direct head impact.

**Clinical and Historical Features**

By the time most patients with minor TBI reach the emergency department, their symptoms are resolving or have completely resolved. The most common complaint after minor TBI is headache. Other common problems are nausea and emesis. Patients may also report transient disorientation, confusion, or amnesia. There has been little research to correlate these symptoms with the presence of intracranial lesions in patients with minor TBI.

Clinical signs and symptoms of minor TBI include amnesia for the impact, a period of disordered awareness (with or without loss of consciousness), and a finite period of post-trauma amnesia.\textsuperscript{68} Retrograde amnesia is impaired information retrieval and begins with and includes the traumatic event. In minor TBI, it generally lasts up to several minutes and then very rapidly resolves. Post-traumatic amnesia (PTA) is impairment of information encoding and therefore does not resolve. PTA is the period of time from the injury to the return of conscious recall: events during this interval are essentially lost to the patient. PTA is a better predictor of injury severity and eventual outcome than the duration of retrograde amnesia or GCS.\textsuperscript{68}

Patients with minor TBI often have balance deficits, impaired verbal memory, delayed language comprehension, and slowed speech.\textsuperscript{69} These subtle findings can be overlooked unless a careful and complete neurologic and mental status examination is performed.

Approximately 5\% of minor TBI patients presenting to the emergency department with a GCS of 15 have abnormal CT scans.\textsuperscript{70} This estimate is probably inflated since at least 25\% of minor TBI patients never seek medical care. The incidence of life-threatening lesions that require neurosurgical intervention following minor TBI is less than 1\%;\textsuperscript{68} the goal of emergency evaluation and management of patients with minor TBI is to identify these high-risk patients. Further diagnostic workup hinges on risk stratification in patients with minor TBI (Box 38-3). The criteria are based on several large studies, but because of inconsistent methodology and reporting, they have limitations. For example, loss of consciousness (LOC) in minor head trauma has historically been considered a risk factor for...
A major and controversial decision regarding the emergency management of minor TBI is whether imaging studies should be performed. Several approaches have been described, but the research behind these suggestions remains confusing primarily because of differences in study populations, definitions, and methods. Because they consult on a selected, more injured set of minor TBI patients, neurosurgeons often advocate liberal CT scanning of most patients with minor TBI with a history of LOC (duration not clearly defined) or with amnesia for the traumatic event. Others advocate only hospital observation because the yield of initial abnormal scans requiring acute neurosurgical intervention is low, but patients who do deteriorate after minor head trauma have substantial morbidity and mortality. If resources allow, prolonged emergency department observation may be practical in some circumstances. For example, intoxicated patients with minor TBI who otherwise fulfill low-risk criteria should undergo meticulous serial evaluations in the emergency department until clinical sobriety is achieved. In these patients, a CT scan may be unnecessary, and observation is beneficial.

The most practical approach regarding imaging in the emergency department patient is probably selective CT scanning or observation based on risk stratification of the minor TBI patient. If the low-risk patient is fully awake and not intoxicated, has no focal neurologic findings, has no clinical evidence of skull fracture, and can be kept under competent observation for 12 to 24 hours, neuroimaging is usually not indicated. Patients with moderate-risk minor head trauma (see Box 38-3) should probably undergo CT scanning or prolonged emergency department observation. Studies have prospectively identified and validated high-risk criteria for adult patients with minor head trauma that correlate with increased likelihood of intracranial lesions. These include the presence of a headache, vomiting, age older than 60 years, drug or alcohol intoxication, short-term memory deficits, external signs of trauma above the clavicles, and post-traumatic seizures. A CT scan should therefore be considered for patients with these high-risk findings as well as the other criteria listed in Box 38-3.

Skull radiography after head trauma in adults has been largely replaced by more sophisticated imaging, when imaging is performed. Facial, scalp, or external signs of head trauma by themselves do not predict TBI and are not indications for screening skull radiographs. The presence of a skull fracture suggests significant impact to the head, and therefore an increased likelihood of intracranial lesions. These include the presence of a skull fracture, vomiting, age older than 60 years, drug or alcohol intoxication, short-term memory deficits, external signs of trauma above the clavicles, and post-traumatic seizures. A CT scan should therefore be considered for patients with these high-risk findings as well as the other criteria listed in Box 38-3.

Although CT scanning is extremely sensitive for acute blood, MRI is more sensitive than CT for detecting diffuse axonal injury, ischemia after TBI, and some hemorrhagic lesions, especially those located at the base of the skull or in the posterior fossa. Functional imaging, such as positron emission tomography (PET), can provide information on the metabolic and neurochemical state of the injured brain. Many studies suggest that significant long-term neuropsychiatric sequelae after minor head trauma can occur despite an initial negative head CT scan, and these may be related to lesions seen initially only by MRI or functional imaging. Functional imaging is not currently within the scope of emergency assessment of minor TBI patients, but it can direct rehabilitation strategies for the small subset of patients who suffer significant morbidity after minor TBI.

Ancillary Studies
No routine laboratory tests are needed for patients with isolated minor head trauma. A urine toxicology screen and blood
alcohol level may be useful in interpreting the patient’s mental status. Alcohol can affect the GCS, but this effect is not observed until the blood alcohol concentration is greater than 200 mg/dL; until that level, changes in mental status cannot be explained solely by acute alcohol intoxication.68

A number of CNS biomarkers, such as S-100B, neuron-specific enolase, myelin basic protein, cleaved tau, and creatine kinase isoenzyme BB, have been investigated in minor TBI. None of these have been shown to strongly correlate with long-term outcome, and only S-100 B predicts abnormal CT findings in minor TBI. However, S-100B appears to lack CNS specificity and is often elevated in multiple trauma patients with no head injury.14 To date, serum biomarkers have lacked the precision needed for meaningful application in the emergency setting.

Disposition

Most patients with low-risk minor TBI can be discharged from the emergency department after a normal examination and a reasonable period of observation (i.e., 4–6 hours).28 If the emergency physician decides that the patient with moderate- or high-risk minor TBI can be sent home, an appropriate early follow-up should be arranged. Patients should be discharged with instructions describing the signs and symptoms of delayed complications of head injury, should have access to a telephone, and should be monitored in the acute post-trauma period by a responsible, sober adult. If any doubt exists regarding the safety of the discharged patient with minor head injury, a brief inpatient observation period (i.e., 12–24 hours) is advisable.

If a patient with minor head trauma returns to the emergency department because of persistent symptoms, delayed complications of minor head injury should be sought. If a CT scan was not performed, the intensity of symptoms may guide the decision to obtain a CT scan at the second visit. If a negative scan was initially obtained, the decision to rescan is more complex. The literature about repeat scanning in minor TBI is scant; however, in one systematic review of severe and moderate TBI, progression of lesions most commonly correlated with overall injury severity and the patients’ use of anticoagulants.74

Concussion. A concussion (or complicated minor TBI) is a type of minor TBI usually caused by acceleration-deceleration or rotational injury to a freely mobile head, and it is most commonly associated with collision sports.24 The injury results in distortion of axons, vasculature, and brain neuroanatomy. As in other types of minor TBI, acute CT or MRI abnormalities are not usually found, but functional imaging (i.e., PET) reveals abnormalities with glucose uptake and blood flow.74,75 Levels of neurotransmitters remain elevated, and a hypermetabolic state may persist in the brain for several days to weeks after the initial injury.

Like patients with minor TBI, concussed patients frequently complain of headaches, dizziness, confusion, and amnesia for the traumatic event and have nonfocal neurologic examinations. Patients with concussion have more severe and persistent symptoms than those with uncomplicated minor TBI. In young children, acute symptoms of concussion differ from those in adults and may include restlessness, lethargy, confusion, or irritability. On presentation, concussed children may be vomiting, tachycardic, or appear pale. These signs and symptoms are usually completely resolved by 6 hours.

Approximately 300,000 yearly sports-related concussions are reported to the Centers for Disease Control and Prevention.76 A study of concussed football players showed acute symptoms lasting at least 5 days, cognitive impairments lasting 5 to 7 days, and balance deficits lasting 3 to 5 days after concussion; 91% were back to their preinjury baseline by 7 days, but some had deficits on verbal fluency tests as long as 90 days after injury.76

The demonstrated period of neurodysfunction and the delayed return to cognitive and physical baseline that follows concussive impact have led to the development of several scoring systems to grade severity of concussions with the goal of determining when it is safe for an athlete to return to play. No single set of guidelines has emerged that has been universally accepted, but all are predicated on the concern about a period of vulnerability following impact. Football players sustaining concussion appear susceptible to an additional concussion, with the majority of reinjury occurring within 10 days after the first injury. This is variably attributed to balance defects, delayed reflexes, delayed speed of information processing, or simply because of continued exposure to collision sports.75,76

The second impact syndrome (SIS) occurs when an athlete sustains a second concussion before being completely asymptomatic from the first and then experiences a rapid, usually fatal, neurologic decline. It is postulated that persistent neurochemical disturbances and altered autoregulatory mechanisms after a first injury make the brain particularly vulnerable to marked brain swelling and subsequent herniation after a seemingly minor second impact. Although the existence and frequency of the SIS are controversial and debated in the sports medicine literature, its serious implications affect subsequent management decisions regarding head-injured athletes and others with concussion.67,74,75 All current recommendations for return to play after a sports-related concussion state that players with concussion should not return to play for at least 1 week after they have become asymptomatic. This is usually increased to at least a symptom-free month if an LOC or prolonged post-traumatic amnesia occurred at the time of concussion.

Almost all patients with minor TBI will have rapid and complete resolution of their symptoms,77 and there is currently no good evidence that uncomplicated minor TBI leads to long-term sequela.68 However, a subset of patients with concussion report symptoms that persist for long periods after trauma. These persistent symptoms are called the postconcussive syndrome (PCS). The incidence of PCS is reported to be 10 to 25%,14,68,78 but these estimates are based on inpatient studies and are therefore likely to be high.

The most common delayed or persistent postconcussive complaints are headache, sensory sensitivity, memory or concentration difficulties, irritability, sleep disturbances, and depression. It was long believed that persistent postconcussive symptoms were psychosomatic, litigious, or factitious, and it is likely that the manifestation and expression of PCS depend on factors in addition to injury severity, such as preinjury physical and mental health.68 However, the presence of abnormalities on functional imaging and with sophisticated neuropsychometric testing suggests a pathophysiologic basis for PCS.15,79 Studies of concussed athletes (for whom preinjury baseline data are available) show that the cognitive domain most frequently involved in PCS is memory.14 Dizziness occurring early after trauma is associated with a prolonged PCS.72

Management and Disposition

The management decisions faced by the emergency physician are the same as those addressed when evaluating all patients with apparently minor TBI: extent of workup to initiate in the
emergency department and whether the patient can be safely discharged home. Emergency department patients who have a sports-related concussion should probably not be allowed to return to play from the emergency department; current recommendations are for a gradual progressive return to play. Many authorities suggest follow-up at 1 week to determine the duration of symptoms and when the patient can safely return to sports. The possibility of PCS should be considered in all concussed patients, regardless of their initially benign presentation, and it may be prudent to suggest scheduled primary care follow-up for reassessment if symptoms persist.

### Pediatric Head Injuries

#### Epidemiology

Approximately 650,000 children ages 0 to 19 years are emergently evaluated yearly in the United States for head trauma, with approximately 65,000 hospital admissions and 7500 fatalities. TBI accounts for the largest source of childhood mortality and morbidity after trauma. In children, transportation-related injuries or falls account for most head trauma. Child abuse is a common etiology of head injury in young children. Duhaime and colleagues found that nearly 25% of head-injured children younger than 2 years of age had inflicted injuries. In head-injured children younger than 1 year of age, as many as 66% of all injuries and 95% of severe injuries may be nonaccidental.

#### Pathophysiology

Until the cranial sutures close, children’s skulls are more displaceable than those of adults. As a result, young children may often sustain less TBI after head trauma than adults with comparable nonfatal mechanisms of injury. However, children appear to have an age-dependent brain vulnerability. Very young children (younger than 1 year) have higher mortality after head trauma than older children with the same severity of injury. Many factors contribute to this. Medical attention is often delayed in children with nonaccidental injuries. Because of limited language and comprehension, an accurate formal neurologic examination in young children is sometimes difficult. Medical personnel tend to underestimate the extent of the injuries in small children and are often reluctant to initiate invasive procedures that may be necessary to aid in the diagnostic workup, such as IV access for sedation in CT scanning.

The types of TBI sustained after head trauma in children differ from those in adults. Children have fewer traumatic mass lesions (with the exception of subdural hematomas in the very young), fewer hemorrhagic contusions, more diffuse brain swelling, and more diffuse axonal injury. Of head-injured patients younger than 20 years of age who talk and deteriorate, 39% have brain swelling only (i.e., no mass lesions), whereas 87% of patients older than 40 who talk and deteriorate have mass lesions.

#### Clinical Features

As with adults, an accurate description of the mechanism of injury, the appearance of the child immediately before and after the injury, and subsequent events can provide useful information to assist in the evaluation and management of the acutely head-injured child.

In principle, the acute neurologic assessment of head-injured children is the same as that of adults. Pupillary respon-
Many attempts have been made to derive clinical prediction rules for high-risk minor TBI in children. However, unless there is both high sensitivity and high specificity, such rules may actually result in an increased number of CT scans being performed. There is no evidence to suggest that aggressive fluid resuscitation exacerbates cerebral edema in head-injured children. Occult blood loss from multiple trauma should be considered as a possible cause of hypoperfusion. Spinal injury causing shock should also be considered. In children, unlike adults, hypovolemic hypotension can occur because of head trauma. Hypotension from intracranial bleeding can occur in children younger than 1 year of age with a large linear skull fracture and an underlying large epidural hematoma. The intracranial blood can seep through the fracture and produce a large galeal or subperiosteal hematoma. Hypotension from intracranial bleeding can also occur in a child with hydrocephalus and a functioning shunt. Blood may accumulate without much evidence of increased ICP. Scalp lacerations can also produce significant hemorrhage and subsequent hypotension.

Up to 80% of children with severe head trauma have elevated ICP. In infants, a bulging fontanel suggests elevated ICP. Other signs of elevated ICP include bradycardia, papilledema, declining level of consciousness, and seizures. When increased ICP is indicated by physical examination, methods to reduce ICP should be initiated. As with adults, acute hyperventilation has immediate effects but is never indicated for prophylaxis or for prolonged management of increased ICP. Hyperosmolar therapy is effective at reducing ICP. Although efficacy studies were based on adults, mannitol at doses of 0.25 to 0.5 g/kg has become a mainstay in the treatment of elevated ICP in children with severe TBI. Several studies support the effectiveness of hypertonic saline in lieu of mannitol for elevated ICP in pediatric head-injured patients. Treatment is with a continuous infusion of 3% normal saline at between 0.1 and 1.0 mL/kg body weight, titrated to effect. Severely head-injured children are less likely to have a surgically amenable lesion than adults. Because diffuse brain swelling is the most common finding in severely head-injured children, emergency burr holes are generally ineffective.

When considering minor head injury in children, it is important to differentiate children younger than age 2 years and older children. Children younger than age 2 years with traumatic brain injuries are often difficult to assess and may have subtle clinical findings. In general, the literature supports the conclusion that younger patients are at higher risk for intracranial injury. One clinical sign of potential brain injury in children younger than age 2 years is the presence of a scalp hematoma, especially a large parietal scalp hematoma. In an observational cohort study involving children with low risk for brain injuries, scalp hematomas were present in 95% of children 2 years old or younger who had brain injuries.

The CT scan is the diagnostic imaging modality of choice in the evaluation of moderate or severe pediatric TBI. It should also be strongly considered in pediatric patients with high-risk minor TBI. However, potential risks are associated with childhood exposure to radiation. Children are more sensitive to radiation than adults because of rapidly dividing cells occurring during growth. The younger the child, the more potential risk. Increased rates of cancer and decreased cognitive performance and academic development have been associated with radiation doses similar to that of a single head CT scan. An additional safety concern is the frequent need to sedate young children in order to obtain an adequate imaging study. In these circumstances, the risks of radiation exposure and sedation should be weighed against the likelihood of an intracranial lesion in the child with minor head trauma.

Many attempts have been made to derive clinical prediction rules for high-risk minor TBI in children. However, unless there is both high sensitivity and high specificity, such rules may actually result in an increased number of CT scans being performed.
performed. Clinical predictors for increased risk of intracranial lesions in children with minor TBI have been described and can help with risk stratification. A meta-analysis including more than 22,000 children suggested that the presence of a skull fracture, focal neurologic signs, documented loss of consciousness, and a presenting GCS score of less than 15 were statistically associated with TBI.91,92 Many authorities also include a history of protracted vomiting, abnormal mental status or lethargy, obvious scalp hematomas in children 2 years old or younger, and progressively worsening headache.85

The use of skull radiographs in the diagnostic workup of head-injured children is controversial but may be appropriate in some circumstances. As with adults, when a CT scan is indicated, skull radiographs are not necessary. Up to 11% of children younger than age 2 years will sustain a skull fracture associated with head trauma, and 15 to 30% of these will have TBI. Therefore, in children younger than age 2 years, a skull fracture is a predictor of TBI.93 The presence of a skull fracture in children significantly increases the likelihood of intracranial pathology; conversely, a negative radiographic skull screen does not guarantee the absence of TBI. Parietal skull fractures are the most common. Often, fractures occur in infants who sustain relatively minor head injury. Skull films may be useful as a screening tool in determining the need for a CT scan, especially in children 2 years old or younger whose neurologic examination is difficult to obtain and interpret. In alert children younger than age 2 years with minor head injury, a low-risk history, a normal physical examination that includes a normal neurologic and mental status examination appropriate for age, and a scalp hematoma, skull radiographs may be a useful screen.85 If the skull radiograph is negative for a fracture, a CT scan may be unnecessary. If the skull radiograph shows a fracture, CT imaging is indicated.

In older children, skull radiographs are rarely useful unless a specific lesion is suspected, such as a depressed skull fracture or a penetrating foreign object. Skull fractures are more clinically significant in children than in adults. Fractures, especially complex stellate or multiple injuries, are often seen in abused children, and skull films should be obtained if abuse is suspected. Ping-pong fractures occur with concentrated forces that indent the skull. These fractures are unique to infants and appear as multiple indentations in the skull with no significant bone discontinuity. Skull fractures are common in children who have sustained deep scalp lacerations or who have a large scalp hematoma.

Leptomeningeal cysts or growing skull fractures are delayed complications of linear skull fractures in infancy. If a tear in the dura accompanies the linear fracture, the meninges may fill with CSF and prolapse through the fracture margins, thus preventing fracture healing.85 These cysts can grow in size and have the potential to cause a mass effect. If a linear fracture is found by skull radiography, close follow-up is indicated to assess for this delayed complication.

Overall, children who sustain severe head injury have lower mortality and a better neurologic outcome than comparably injured adults. This is probably because of the neuroplasticity of the young brain; however, in children younger than age 2 years, the prognosis after severe head injury is poor.89 Very young children have immature cerebrovascular autoregulation, which increases the risk of cerebral edema formation. The immature brain has increased susceptibility to permanent injury because of incomplete myelination.

The emergency evaluation of children with minor head injury is especially challenging, given their potentially dramatic presentation and the added difficulty of obtaining an accurate neurologic assessment. Evidence-based consensus guidelines have been proposed for the evaluation and management of minor head injury in children.85,86 Disposition of pediatric patients with minor head injury is summarized in Box 38-5. Parents should be educated about the warning signs and symptoms of delayed complications of minor head trauma.

### PENETRATING HEAD INJURIES

#### Epidemiology

Penetrating brain injury (PBI) occurs at a rate of 12 per 100,000 population and can be sustained by missile injuries or impalement.94 The United States has the highest penetrating head injury rate among developed countries in the world, with the most common cause being gunshot wounds (GSWs). These dramatic injuries are increasing in frequency, and the neuroscientific understanding of the complicated cerebral events that occur with penetrating head injury does not yet equal our understanding of the pathophysiology of blunt injuries.
Civilian GSWs to the head account for approximately 21,000 deaths per year, and up to 66% of all patients who sustain a GSW to the head are dead at the scene.83 Overall, the mortality caused by a GSW to the head is estimated to be 90%.83 If the patient is hemodynamically stable, has not sustained secondary systemic insults such as hypoxia or hypotension, has no expanding mass lesions from the missile injury, and has not ingested intoxicants that may interfere with assessment, prognosis after a GSW to the head can be predicted by the presenting GCS and pupillary responsiveness.97 If the presenting GCS is less than 5, mortality approaches 100%. If the presenting GCS is greater than 8 and the pupils are reactive, survival approaches 75%. Survivors of GSW to the head tend to do well, with up to 60% returning to their former employment.97

Pathophysiology

Missile injuries to the head can result in several different patterns of damage. Tangential wounds are caused by an impact that occurs at an oblique angle to the skull. If the missile has high velocity but low energy, it can travel around the skull under the scalp without passing through the skull. Intracranial damage, primarily cortical contusions, can occur at the initial site of impact because of pressure waves generated by the impact. In one study, 24% of patients with tangential GSWs also had intracranial hemorrhage, and 16% sustained skull fractures.98 Perforating wounds are usually caused by high-velocity projectiles, which cause through-and-through injuries of the brain with an entrance and an exit wound. This type of injury is largely discussed within the context of military GSWs to the head. In cases of complete traversal (through-and-through) GSW to the head, the entrance wound is usually smaller than the exit wound.

Penetrating missile wounds are produced with moderate-to high-velocity projectiles discharged at close range. The majority of the civilian PBI literature deals with penetrating missile wounds.96 The penetrating object may travel through the entire skull, bounce off the opposite inner table of the skull and ricochet within the brain, or stop somewhere within the cranial cavity. Bullets that penetrate the skull do not travel in a straight path. The wounding capacity of a firearm is related to the kinetic energy of its missile on impact and how much energy is dissipated in the tissues. Low-velocity missiles tend to be deflected by intracranial structures. The final track is air sucked into the penetration cavity behind the projectile. Flight stability and the angle at which the bullet strikes its target affect the path through the brain. Within tissue, destabilizing motions include deviation of the longitudinal axis of the bullet from a straight line (yaw), forward rotation of the bullet around its center of mass (tumbling), and oscillatory motion of the bullet axis around its center of mass (rotation). As the bullet passes through the brain, a tissue cavity is created. This cavity can be as much as 10 times the diameter of the missile. A concussion shock wave is also created, lasting 2 msec but causing little tissue destruction.96

The morbidity and mortality from missile injuries to the head depend on the intracranial path, speed of entry, and the size and type of the penetrating object. Projectile that cross the midline or the geographic center of the brain, pass through the ventricles, or come to rest in the posterior fossa are associated with extremely high mortality.94 High-velocity wounds are associated with greater mortality than low-velocity injuries. Large missiles or missiles that fragment within the cranial vault are usually fatal. The design of the bullet and its fragmentation potential (capacity to deform or fragment) also contribute to final tissue destruction and patients’ morbidity and mortality.

Many GSWs to the head are intentionally self-inflicted injuries. The percentage of penetrating head injuries caused by self-inflicted GSWs ranges from 13 to 88%.97 Characteristics of self-inflicted GSWs include injury on the dominant side, powder burns at the entrance site, and large stellate scalp lacerations caused by dissection of the subgaleal layer by exploding gases released close to the scalp. In suicide attempts, GSWs to the head tend to traverse the midline in the coronal plane and often involve major vascular structures. If the self-inflicted GSW has an entrance through the mouth, injury to the hard palate may occur with potential upper airway compromise. The careful aim and close range of self-inflicted GSWs to the head make these injuries particularly devastating; mortality is higher than with non-self-inflicted penetrating injuries, and odds ratios of death vary between 1.63 and 5.83.97

Clinical Features

Physical assessment of the patient with a missile wound to the head focuses on the presenting GCS and pupillary responsiveness. In addition to the physical damage to brain tissue caused by the penetrating injury, other devastating physiologic changes occur immediately after injury. ICP increases, the BBB breaks down, CBF is altered, and cerebral edema develops. Cerebral autoregulation is lost, and CPP may fall.

Management

The emergency department management is directed at reducing the occurrence of the secondary systemic insults of hypoxia and ischemia, with emergent intervention if signs of herniation syndrome develop and the patient is viable. Management should be aggressive until the prognosis can be established by examination and neuroimaging data. When penetration of the cranial vault is established, the patient should be intubated. If the physician waits for coma before intubating the patient, mortality approaches 100%.99

Emergency treatment should include IV antibiotics because penetrating missiles are contaminated with skin, bone, and hair. Tissue contamination may be widespread because of the cavitation caused by the missile as it passes through the brain.100 Approximately 90% of all CNS infections associated with penetrating TBI injuries occur within 6 weeks. Most neurosurgeons do not automatically débride bone and missile fragments due to a growing body of literature that shows no evidence that removal of these foreign bodies decreases infection rate.15

Between 30 and 50% of patients with PBI develop seizures; 10% of these occur in the first week.17 Anticonvulsants should be given in the acute setting to prevent early post-traumatic seizures in the patient with PBI, especially if the patient is to be transported to another institution after acute stabilization. Anticonvulsants should not be given beyond the first week after PBI because this has not been shown to prevent the development of late seizures.

Skull radiographs may be useful in determining the number of penetrating fragments and their track. A CT scan defines the precise location of the missile, its intracranial path, the presence of bone or missile fragments, extra-axial or intracerebral blood collections or other traumatic lesions, and pneumocephalus. CT scanning is the radiologic test of choice for PBI.105 Pneumocephalus is often associated with missile wounds that penetrate the sinuses but can be caused by free air sucked into the penetration cavity behind the projectile.
When a penetrating head injury is caused by impalement, the penetrating object should be left in place to be removed at surgery. A skull radiograph shows the size of the object, the angle of impalement, and the depth of penetration. Angiography may be indicated to better discern location referable to key vascular structures.

**COMPLICATIONS AFTER HEAD INJURY**

**Neurologic Complications**

**Seizures**

Post-traumatic seizures are relatively common in the acute or subacute period. Acute post-traumatic seizures are usually brief and are probably caused by transient mechanical and neurochemical changes within the brain. After the acute seizure, the patient often has no additional seizure activity. In the subacute period, 24 to 48 hours after trauma, seizures are caused by worsening cerebral edema, small hemorrhages, or penetrating injuries. Post-traumatic seizures are common in children and can be precipitated by relatively minor head injury.64 Acute post-traumatic seizure prophylaxis in the emergency department is recommended for some head-injured patients even if they have not had a seizure (see Box 38-2).3,310 This is especially important in patients who will have neuromuscular blockade to facilitate management or transfer because the clinical manifestations of seizures are lost in these patients. Phenobarbital (18–20 mg/kg) is used as a first-line agent for prophylaxis. The decision to maintain the head-injured patient on long-term anticonvulsant therapy during the recovery period depends on the patient’s subsequent course. Long-term seizure prophylaxis is not indicated for all patients who have had post-traumatic seizures in the acute or subacute period. The utility of prophylactic anticonvulsants to prevent late post-traumatic seizures has not been proved, and their use is not recommended.102

**Central Nervous System Infections**

*Meningitis after Basilar Fractures.* Post-traumatic meningitis is caused by a variety of microbes, depending on the portal of bacterial entry. Patients present with typical signs and symptoms of meningitis, including fever, altered mental status, and ocasional focal neurologic signs. In patients with a CSF leak after basilar fracture, early meningitis (i.e., within 3 days of injury) is usually caused by pneumococci. Ceftriaxone or cefotaxime is a reasonable antibiotic choice with the addition of vancomycin. Gram-negative organisms often cause meningitis that develops more than 3 days after trauma.103 A third-generation cephalosporin, with nafcillin or vancomycin added to ensure coverage of *Staphylococcus aureus*, should be started. In children, post-traumatic meningitis may be caused by *Haemophilus influenzae*. Prophylactic antibiotics are not currently recommended in the acute setting in patients with CSF leaks caused by basilar skull fractures.102

**Brain Abscess.** Brain abscesses develop infrequently after penetrating missile injuries to the head. Abscesses can also develop after open depressed skull fractures if bone fragments are not removed or as a postoperative complication. Post-traumatic CSF fistulae and fractures that disrupt air-filled sinuses predispose to the formation of brain abscesses. Clinical manifestations include headaches, nausea, vomiting, declining mental status, signs of increased ICP, or new focal neurologic findings in patients who had been improving after trauma. Occasionally, nuchal rigidity, hemiparesis, or seizures may be present. Systemic signs are often subtle, and CSF leukocytosis may be absent.

Contrast-enhanced CT scanning makes the diagnosis of brain abscess. A ring pattern with a low-density center is characteristic. The enhanced ring represents surrounding altered vascular permeability and therefore is also seen in the cerebritis stage early in abscess formation. Lumbar puncture is often not helpful and should not be performed in the patient with signs of increased ICP (e.g., headache, vomiting, and papilledema). The treatment of brain abscess is usually operative drainage. The patient with cerebritis may respond to IV antibiotics but requires close monitoring with repeated CT scans. Common organisms isolated from post-traumatic abscesses are *S. aureus* and gram-negative aerobes.103

**Cranial Osteomyelitis.** Cranial osteomyelitis can occur after penetrating injury to the skull. The clinical manifestations include pain, tenderness, swelling, and warmth at the infected site. More than 50% of cases are obvious on plain skull radiographs.103 Technetium bone scans can help in the diagnosis when the skull radiographs are negative, but false-positive bone scans occur in patients with previous trauma or craniotomy. Adding a gallium scan helps to differentiate infection from other causes of a positive technetium scan. Patients with post-traumatic cranial osteomyelitis require surgical débridement and removal of the infected bone. Antibiotic choice is determined by culture results. If systemic symptoms are present, an underlying subdural or epidural empyema is often present.

**Medical Complications**

**Disseminated Intravascular Coagulation**

The injured brain is a source of tissue thromboplastin that activates the extrinsic clotting system. Disseminated intravascular coagulation (DIC) can develop within hours after any injury disrupting brain tissue. It has been detected in nearly all patients with severe TBI.65 DIC increases morbidity and mortality after severe head trauma as well as the risk of delayed intracranial hemorrhage. If a stable patient with DIC suddenly deteriorates, a repeat CT scan should be obtained to rule out hemorrhage.

The extent of tissue destruction determines the degree of DIC that develops. The diagnosis is based on abnormalities in international normalized ratio, prothrombin and partial thromboplastin time, platelets, plasma fibrinogen levels, and fibrin degradation products. Patients with coagulopathy or abnormal platelet function require interventions to correct these.

**Neurogenic Pulmonary Edema**

Neurogenic pulmonary edema can develop from minutes to days after head trauma. This noncardiac pulmonary edema probably results from altered hydrostatic forces and microvascular permeability directly caused by brain injury. Lowering the ICP appears to reverse the neurogenic stimulation that causes this edema.104

**Cardiac Dysfunction**

A variety of cardiac rhythm, rate, and conduction abnormalities are detected after head injury. These abnormalities can be life threatening and require aggressive therapy. In addition, adequate cardiac output is essential in head-injured patients to ensure cerebral perfusion. Many head-injured patients with cardiac dysfunction have concurrent myocardial injury from underlying disease or from chest injury. However, brain injury
Scalp lacerations are extremely common after head injury and may be a source of significant bleeding because hemostasis may be difficult to achieve. Methods include direct digital compression of the bleeding vessel against the skull, infiltration of the wound edges with lidocaine with epinephrine, and ligation of identified bleeding vessels. If the galea is lacerated, it can be pulled up with a clamp and its edges folded over the lacerated skin edges to tamponade the bleeding vessels. Raney scalp clips applied to the edges of the wound are also effective. In stable patients, quick closure of the wound, after proper débridement and irrigation, is the most effective way to stop a bleeding scalp laceration and prevent the tissue crush injury that may occur if other compressive methods are used for too long. Obviously, in unstable patients, higher priority interventions take precedence over wound care.

When hemostasis is obtained, the wound should be irrigated to rinse away any debris. The emissary vessels of the subgaleal layer of the scalp drain directly into the diploe veins of the skull. These in turn drain into the venous sinuses. Contaminations take precedence over wound care.

Scalp abrasions are often contaminated with pieces of dirt or other debris. The wound should be cleaned as thoroughly as possible and inspected for puncture wounds or other areas that penetrate beyond the superficial layers of the skin to ensure the removal of unsuspected foreign bodies. A careful inspection often reveals a small scalp laceration within the abraded area. Antibiotics are usually not needed for carefully managed scalp wounds because rapid healing is facilitated by the rich blood supply of the scalp.

Skull Fractures

Clinical Assessment and Significance

Skull fractures are local injuries caused by direct impact to the skull. The presence of a skull fracture does not always indicate underlying brain injury. However, the force required to fracture the skull is substantial, and all cases of skull fracture must be carefully evaluated to ensure that no additional injury is present. With increasing severity of head injury the likelihood of skull fracture increases, and the presence of a skull fracture after trauma increases the likelihood of having a TBI. It is often difficult to predict the presence of a skull fracture by clinical examination, and if this can be done, it is likely that substantial underlying brain injury is also present. The pattern, extent, and type of skull fracture depend on the force of the impact applied and the ratio of the impact force to the impact area. The fracture usually starts at the point of maximum impact.

Clinically significant skull fractures result in intracranial air and pass through an air-filled space (e.g., sinus), are associated with an overlying scalp laceration (open skull fracture), are depressed below the level of the skull’s inner table, or overlie a major dural venous sinus or the middle meningeal artery. Plain radiographs are most useful in demonstrating a depressed skull fracture, the depth and extent of a penetrating injury, or the presence of an intracranial foreign body. A CT scan with bone windows also demonstrates these findings; therefore, patients undergoing CT do not require skull radiographs.

Linear Fractures

A linear skull fracture is a single fracture that goes through the entire thickness of the skull. Linear skull fractures are clinically important if they cross the middle meningeal groove or
major venous dural sinuses; they can disrupt these vascular structures and cause the formation of epidural hematomas. Most other linear skull fractures are not clinically significant.

It is sometimes difficult to distinguish linear skull fractures demonstrated on radiographs from cranial sutures. In general, fractures are more lucent than vascular grooves and sutures. Sutures are usually less than 2 mm wide in adults; fractures are often 3 mm or greater in overall width and tend to be widest in the midportion and narrow at each end. Linear fractures are most common in the temporoparietal, frontal, and occipital regions of the skull and can usually be visualized on more than one radiographic view. In children, skull fractures heal within 3 to 6 months; in adults, complete healing may take up to 3 years.

Sutural diastasis is the traumatic disruption of a cranial suture. In adults, sutural diastasis often involves the coronal or lambdoid sutures. Sutural diastasis usually occurs when a linear fracture extends into the suture line, and it is rare after sutures have undergone bone fusion.

Comminuted skull fractures are multiple linear fractures that radiate from the impact site. Usually, this injury suggests a more severe blow to the head than that producing a single linear fracture.

A linear vault fracture substantially increases the risk of intracranial injury. If any skull fracture is detected, a CT scan should be obtained, and the patient should be carefully observed for delayed complications of head trauma.

Depressed Fractures

Depressed skull fractures are clinically important because they predispose to significant underlying brain injury and to complications of head trauma, such as infection and seizures. When a depressed fracture occurs, traumatic impact drives the bone piece below the plane of the skull. The edges of the depressed portion of skull may become locked underneath the adjacent intact bone and fail to rebound into their previous position. As a result, the depressed piece of bone can penetrate tissue and lacerate the dura. Depressed skull fractures are usually caused by direct impact injury with small blunt objects, such as a hammer or a baseball bat. Most depressed skull fractures occur over the parietal or temporal regions. If the free piece of bone is depressed deeper than the adjacent inner table of the skull, most neurosurgeons consider this injury significant enough to require surgical elevation.

On skull radiographs, depressed fractures may be difficult to visualize. The free piece of bone demonstrates increased or double density because it often overlaps the nonfractured bone or it is viewed relatively rotated from the rest of the adjacent cranium. Tangential views of the skull may increase the ability to visualize the fracture.

Depressed skull fractures can often be felt with palpation of the skull beneath a scalp laceration. This examination should be done cautiously to avoid driving a depressed bone fragment deeper into the cranial tissue. The clinical examination for a depressed skull fracture may be misleading. The mobility of the scalp can result in nonalignment of the fracture with an overlying scalp laceration. As a result, the skull underlying the laceration may be normal, with the depressed area several centimeters away. Scalp swelling may also interfere with physical examination findings and hide any palpable bone defects. The signs and symptoms of a depressed skull fracture depend on the depth of depression of the free bone piece. Approximately 25% of patients sustaining a depressed skull fracture report LOC. Neurologic deficits may be present, depending on the extent of underlying brain tissue injury.

A CT scan is indicated for patients with a history or physical examination that suggests a depressed skull fracture. The CT scan should include bone windows to determine the depth of depression and the presence of concurrent traumatic intracranial lesions. Patients with depressed skull fractures should be admitted for continued observation by a neurosurgeon.

Depressed skull fractures may increase the risk for developing seizures. Emergency department patients suspected of having a depressed skull fracture warrant prophylaxis for post-traumatic seizures, especially if they have an altered level of consciousness or require chemical paralysis. Depressed skull fractures may also increase the risk for meningitis.

Basilar Fractures

Basilar fractures are linear fractures at the base of the skull. The fracture usually occurs through the temporal bone, with bleeding into the middle ear producing hemotympanum. Often, the fracture has caused a dural tear, which produces a communication between the subarachnoid space, the paranasal sinuses, and the middle ear. This offers a route for the introduction of infection into the cranial cavity and is suggested by a CSF leak. As with linear skull fractures, a basilar fracture is not always associated with significant underlying brain injury; these fractures are the result of considerable impact force, however, and TBI must be ruled out.

Basilar fractures can compress and entrap the cranial nerves that pass through the basal foramina, can dislocate the bones of the auricular chain, and can disrupt the otic canal or cavernous sinuses, with subsequent injury to cranial nerves III, IV, and V. Fractures of the sphenoid bone can disrupt the intracavernous internal carotid artery, creating the potential for the formation of pseudoaneurysms or carotid venous fistulae. The diagnosis of a basilar skull fracture is based on associated clinical signs and symptoms (see Box 38-1).

Skull radiographs do not detect basilar fractures well. All patients with clinical evidence suggesting a basilar skull fracture should have a CT scan to define the fracture and to rule out concurrent intracranial pathology, and they should be admitted for observation. Because the basilar skull fracture may afford an entrance for bacteria, antibiotics are often considered. However, most CSF leaks resolve spontaneously with no complications in 1 week, and antibiotics generally are not given prophylactically during the first week of CSF rhinorrhea. If a patient with a previously diagnosed CSF leak returns to the emergency department with fever, the diagnosis of meningitis should be strongly suspected and appropriate workup (i.e., lumbar puncture) and antibiotic treatment initiated immediately. A rare but significant complication of basilar skull fracture is traumatic carotid cavernous fistula (TCCF). In a retrospective review, the overall incidence of TCCF in basilar skull fractures was 3.8%, with middle fossa basilar skull fractures having the highest association.

Open Fractures

A skull fracture is open when a scalp laceration overlies a fracture. If the fracture has disrupted the dura, a communication exists between the external environment and the brain. A fracture that disrupts the paranasal sinuses or the middle ear structures is also considered open. An open skull fracture requires careful irrigation and débridement. Blind probing of the wound should be avoided because it can introduce contaminants into the wound and can further depress comminuted fracture pieces.
Diffuse Axonal Injury

Prolonged traumatic coma not caused by mass lesions, ischemic insult, or nontraumatic causes of coma is thought to result from diffuse axonal injury (DAI). DAI is a pathologic process in which axons are stretched and twisted by the same shear and tensile biomechanical forces that produce concussion. Effected axons are dispersed between areas of undamaged cells. Badly damaged axons become edematous and eventually begin to separate from each other, causing widespread disruption of cortical physiology and microanatomy in the white matter of the brain and brainstem. Complete separation of axons does not always cause cell death; acute uncoupling of cerebral blood flow and metabolism and apoptosis are thought to be the primary factors linked to axonal cell death after DAI. Recovery depends on the reversal or correction of structural and physiologic abnormalities.14

DAI is thought to be the cause of persistent traumatic coma that begins immediately at the time of trauma; however, some patients with DAI may recover consciousness briefly before lapsing into prolonged coma. No specific acute focal traumatic lesions are noted on a head CT scan. MRI may be more sensitive in detecting subtle injury in DAI, but it is often not practical to perform MRI on critically injured patients. Occasionally, small petechial hemorrhages in proximity to the third ventricle and within the white matter of the corpus callosum or within the internal capsule of the brainstem are detected. DAI is the most common CT finding after severe head trauma, estimated to occur in 50% of all comatose head-injured patients.108

Because clinical diagnostic studies cannot predict the extent of the axonal damage, the severity of the injury is determined by the clinical course. Patients with mild DAI are in coma for 6 to 24 hours. Approximately one third of patients with mild DAI demonstrate decorticate or decerebrate posturing, but by 24 hours they are following commands.108 The mortality in this group is 15% and is associated with infectious complications or concurrent intracranial injuries. Most patients who recover have mild or no permanent disabilities. Moderate DAI is the most common clinical picture. Patients with moderate DAI are in coma for longer than 24 hours. Often, they are victims of falls or vehicular crashes and have associated basilar skull fractures. Patients may exhibit transient decortication or decerebration but eventually recover purposeful movements. On awakening, patients have prolonged severe post-traumatic amnesia and moderate to severe persistent cognitive deficits. Almost 25% die of complications of prolonged coma.106

Severe DAI is almost always caused by vehicular crashes. Patients remain in coma for prolonged periods and demonstrate persistent brainstem dysfunction (posturing) and autonomic dysfunction (e.g., hypertension and hyperpyrexia). Diffuse brain swelling subsequent to injury causes intracranial hypertension. Herniation syndrome can occur if elevated ICP does not respond to medical or surgical intervention. Some patients with severe DAI eventually awaken but are severely disabled. Some patients remain in a persistent vegetative state, but most with severe DAI die from their head injury. All patients with DAI present identically in coma. No early clinical predictor differentiates patients with mild, moderate, or severe DAI.

Contusions

Contusions are bruises on the surface of the brain, usually caused by impact injury. Most often, contusions occur at the poles and the inferior surfaces of the frontal and temporal lobes where the brain comes into contact with bone protuberances in the base of the skull. If the contusion occurs on the same side as the impact injury, it is a coup injury; if it occurs on the opposite side, the contusion is a contrecoup injury. Contusions also often develop in the brain tissue that underlies a depressed skull fracture. Multiple areas of contused tissue may be produced with a single impact, often in association with other intracranial injuries. Contusions are produced when parenchymal blood vessels are damaged, resulting in scattered areas of petechial hemorrhage and subsequent edema. Contusions develop in the gray matter on the surface of the brain and taper into the white matter. Often, subarachnoid blood is found overlying the involved gyrus. With time, the associated hemorrhages and edema of a contusion can become widespread and serve as a nidus for hemorrhage or swelling, thus producing a local mass effect. Compression of the underlying tissue can cause local areas of ischemia, and tissue infarction is possible if the compression is significant and unrelieved. Eventually, these ischemic areas become necrotic, and cystic cavities form within them.

The clinical presentation of patients with contusions is frequently delayed. They may have sustained only a brief LOC, but the duration of post-traumatic confusion and obtundation may be prolonged. If contusions occur near the sensorimotor cortex, focal neurologic deficits may be present. Many patients with significant contusions make uneventful recoveries, but contusions may cause significant neurologic problems, including increased ICP, post-traumatic seizures, and focal deficits.

Non-contrast-enhanced CT is the best diagnostic test to discover contusions in the early post-traumatic period. These appear heterogeneous and irregular because of mixed regions of hemorrhage, necrosis, and infarction. Often, the surrounding edematous tissue appears hypodense. By post-trauma days 3 and 4, the blood located within the contusions has begun to degrade, and MRI becomes more useful.

 Epidural Hematoma

Epidural hematomas (EDHs) are blood clots that form between the inner table of the skull and the dura. Most EDHs are caused by direct impact injury that causes a forceful deformity of the skull. Often, a fracture occurs across the middle meningeal artery, vein, or a dural sinus. The temporoparietal region is the most likely site for an EDH.24 The high arterial pressure of the bleeding vessel dissects the dura away from the skull, permitting the formation of the hematoma.

An EDH is usually unilateral, and 20% of patients have other intracranial lesions, usually subdural hematomas or contusions.25 The deterioration of a patient who has an EDH from arterial bleeding can be rapid and dramatic. Because of their rapid formation, EDHs from arterial bleeding are usually detected within hours after injury and often earlier in children. EDHs that develop from a dural sinus tear develop more slowly, and clinical manifestations may be delayed, with resultant delays in detection.

EDH is primarily a disease of the young and accounts for 0.5 to 1% of all patients who have experienced TBI.24 EDHs are rare in elders and children younger than 2 years of age because of the close attachment of the dura to the skull in both patient populations. The classic presentation of an EDH is described as head trauma producing a decreased level of consciousness followed by a “lucid” interval. Although the patient’s consciousness is less decreased during the lucid interval, a completely normal mental status may not return before a second episode of decreased consciousness occurs. The lucid interval is not pathognomonic for an EDH and occurs in patients who sustain other expanding mass lesions. In fact, only approx-
approximately 30% of patients with EDHs present classically. The development of symptoms and signs of EDH is entirely dependent on how quickly the EDH is developing within the cranial vault. Patients with an EDH often complain of a severe headache, sleepiness, dizziness, nausea, and vomiting. A small EDH may remain asymptomatic, but this is rare.

If the patient is not in coma when the diagnosis of EDH is established and if the condition is rapidly treated, the mortality is 5 to 10%. If the patient is in coma, the mortality from EDH is approximately 20%. If the EDH is rapidly detected and evacuated, the functional outcome is excellent.

On CT scan, an EDH appears hyperdense, biconvex, ovoid, and lenticular. The EDH does not usually extend beyond the dural attachments at the suture lines. The margins are sharply defined, and the hematoma usually bulges inward toward the brain (Fig. 38-7). EDHs of mixed density on CT may be actively bleeding.

A posterior fossa EDH is the most common traumatic mass lesion of the posterior fossa and accounts for 5% of EDHs. Direct occipital trauma resulting in a skull fracture that disrupts a venous sinus is the usual cause, and most patients have external evidence of occipital injury. Most patients become symptomatic within 24 hours after injury, with complaints of headache, nausea, vomiting, and nuchal rigidity. Most patients eventually have a decreased level of consciousness. On CT scan, a posterior fossa EDH looks similar to other EDHs, but it may cross the midline and extend above the tentorium to the supratentorial compartment (Fig. 38-8). Mortality approaches 26%.

Recent studies have investigated the indications for immediate operative intervention for EDHs. Epidurals greater than 30 cm³ in volume should be evacuated surgically, regardless of the patient’s GCS score. Furthermore, it is strongly recommended that comatose patients with an acute EDH and anisocoria on pupillary examination undergo surgical evacuation as soon as possible.

Subdural Hematoma

Subdural hematomas (SDHs) are blood clots that form between the dura and the brain. Usually, they are caused by the movement of the brain relative to the skull, as seen in acceleration-deceleration injuries. These hematomas are common in patients with brain atrophy, such as alcoholic or elder patients. In these patients, the superficial bridging vessels traverse greater distances than in patients with no atrophy. As a result, the vessels are more likely to rupture with rapid movement of the head. Once they are ruptured, blood can fill the potential space between the dura and arachnoid.

SDHs are more common than EDHs, occurring in up to 30% of patients with severe head trauma. The slow bleeding of venous structures delays the development of clinical signs and symptoms. As a result, the hematoma compresses the underlying brain tissue for prolonged periods and can cause significant tissue ischemia and damage.

The patient’s clinical presentation depends on the amount of brain injury sustained at the time of trauma and the rate of SDH expansion. If the patient with an SDH was rendered unconscious at the time of trauma, the prognosis is poor; these patients often have concurrent DAI. The signs and symptoms after injury that produce an SDH are initially related to the other intracranial injuries that may have been sustained and then to the slow expansion of the SDH.

SDHs are classified by the time to clinical presentation. Acute SDHs are symptomatic within 24 hours after trauma. Patients with acute SDHs often have a decreased level of consciousness. Most patients with an SDH present with a GCS score less than 8. Approximately 12 to 38% of patients will have a lucid period at some point in their presentation. The overall mortality of patients who have an SDH and require surgical intervention is between 40 and 60%.

Because of associated brain injury caused by the SDH, the delay in clinical signs and symptoms, and the more advanced mean age of the at-risk population, the mortality associated with SDH is much higher than that associated with EDH. Pupil inequality, motor deficit, and other signs consistent with increased brain swelling may be present on the initial examination. If the patient is deeply comatose at presentation with flaccidity and without signs of brainstem activity, supportive care should be considered in the emergency department. Subsequent management decisions should be discussed with the patient’s family and the attending neurosurgeon.

If the SDH is very small (only a few millimeters thick at its widest point on CT scan), some neurosurgeons may choose careful observation for these patients. Even a small SDH may be accompanied by extensive brain tissue damage that can cause an increase in ICP sufficient to precipitate a herniation syndrome. Current consensus guidelines recommend that acute SDHs with a thickness greater than 10 mm or a midline shift of more than 5 mm on CT should be evacuated surgically, regardless of the patient’s GCS score. Research indicates that the longer the time between clinical worsening and operative treatment, the worse the patient’s clinical outcome. In these cases, surgical evacuation should be performed as soon as possible.

Unlike EDHs, SDHs often extend beyond the suture lines (Fig. 38-9). An SDH may follow the contour of the tentorium and be detected within the interhemispheric fissure (Fig. 38-
PART II

■ Trauma

Section Two

System Injuries

Impact. Mortality is highest in older people, patients who have a GCS of 8 or less, and in those with signs of acute herniation syndrome on initial emergency department presentation. Posterior fossa SDHs make up less than 1% of all reported SDHs. They are caused by occipital trauma that tears bridging vessels or venous sinuses. Clinical manifestations of posterior SDH vary but usually include nausea, vomiting, headache, and decreased level of consciousness. Occasionally, cranial nerve palsies may be found, as well as nuchal rigidity, cerebellar signs and symptoms, and papilledema. On a CT scan, a posterior fossa SDH does not cross the midline or extend above the tentorium. The outcome of a posterior SDH is very poor.

In children, the presence of an SDH should prompt consideration of child abuse. Many types of injury can produce SDH in children, but the infant who is repeatedly and forcibly shaken is especially susceptible. Infants may have SDH because of birth trauma. In these cases, the initial clinical manifestation may be a generalized seizure within the first 6 months of life. On examination, the infant may have a bulging fontanel or an enlarged head circumference. A careful history may elicit long-standing constitutional symptoms, such as failure to thrive or lethargy.

Subdural Hygroma

A subdural hygroma (SDHG) is a collection of clear, xanthochromic blood-tinged fluid in the dural space. The pathogenesis of an SDHG is not certain. It may result from a tear in the arachnoid that permits CSF to escape into the dural space or effusions from injured vessels through areas of abnormal permeability in the meninges or in the underlying parenchyma. They may accumulate immediately after trauma or in a delayed manner. Clinically, an SDHG cannot be distinguished from other mass lesions. Often, patients have a decreased level of consciousness or focal motor deficits. They may complain of headaches, nausea, and vomiting. The ICP can increase because of the mass effect, and signs of increased ICP may be present on examination.
On CT scans, SDHGs appear crescent shaped in the extraaxial space. The CT density is the same as that of CSF. Bilateral SDHGs are common. If SDHGs are asymptomatic, observation is reasonable management. Otherwise, they must be surgically evacuated. Mortality varies from 12 to 55% and appears to depend on the severity of other intracranial injury.

**Traumatic Subarachnoid Hemorrhage**

Traumatic subarachnoid hemorrhage (TSAH) is defined as blood within the CSF and meningeal intima and probably results from tears of small subarachnoid vessels. TSAH is detected on the first CT scan in up to 33% of patients with severe TBI and has an incidence of 44% in all cases of severe head trauma. It is therefore the most common CT scan abnormality seen after head injury. Data from the National Traumatic Coma Data Bank demonstrate a 60% unfavorable outcome in severely brain-injured patients in the presence of TSAH compared with a 30% unfavorable outcome if no TSAH occurs. An increased incidence of skull fractures and contusions is found in patients with TSAH compared with patients with no TSAH. The amount of blood within the TSAH correlates directly with the outcome and inversely with the presenting GCS.

Patients may complain of headache and photophobia. A non-contrast CT scan makes the diagnosis, with increased density noted within the basilar cisterns. Blood can also be seen within the interhemispheric fissures and sulci.

TSAH with no other brain injury does not generally carry a poor prognosis. The most serious complication of TSAH is worsening of cerebral vasospasm, which may be severe enough to induce cerebral ischemia. Post-traumatic vasospasm is common, occurring approximately 48 hours after injury and persisting for up to 2 weeks. Calcium channel blockers (e.g., nimodipine and nicardipine) have been used in the acute intensive care unit setting to prevent or reduce vasospasm after TSAH. Although a radiographic reduction of vasospasm is not consistently seen, the overall outcome of patients treated with these agents seems to be improved compared with no treatment.

**Intracerebral Hematoma**

Intracerebral hematomas (ICHs) are formed deep within the brain tissue and are usually caused by shearing or tensile forces that mechanically stretch and tear deep small-caliber arterioles as the brain is propelled against irregular surfaces in the cranial vault. Resulting small petechial hemorrhages subsequently coalesce to form ICHs. Approximately 85% are in the frontal and temporal lobes. They are often found in the presence of extra-axial hematomas, and in many patients multiple ICHs are present. Isolated ICHs may be detected in as many as 12% of all patients with severe head trauma.

The clinical effects of ICH depend on size, location, and whether the bleeding is continuing. ICHs have been reported with all degrees of severity of head trauma. More than 50% of patients with ICH sustain LOC at the time of impact. The patient's subsequent level of consciousness depends on the severity of the impact and coexisting lesions. Combined with contusions, other concurrent lesions, and subsequent perileision edema, an ICH can produce substantial mass effects and precipitate a herniation syndrome (Fig. 38-11).

An ICH may be detected on the first CT scan immediately after injury but often is not seen for several hours or days. Unlike contusions, ICHs are usually deep in the brain tissue and often become well demarcated over time. On CT scan, an ICH appears as a well-defined hyperdense homogeneous area of hemorrhage (Fig. 38-12).
Many patients with an ICH require emergent intervention or surgery to control elevated ICP. Mortality is low in patients who are conscious before surgery; in unconscious patients, mortality approaches 45%.\(^{114,115}\) ICHs that bleed into the ventricles or cerebellum also carry a high mortality rate.

**Traumatic Intracerebellar Hematoma**

Primary traumatic intracerebellar hematomas are rare but can occur after a direct blow to the occipital area. Often, these patients also have a skull fracture or a posterior fossa SDH. Supratentorial contrecoup hematomas and contusions are also common associated findings.

The clinical presentation of an isolated traumatic cerebellar hematoma is similar to that of other posterior lesions. When other traumatic lesions are present, the picture may be quite confusing. The acute management should first address the most clinically significant lesion. The mortality from isolated traumatic intracerebellar hematoma is very high.

### Severe and Moderate Head Injuries

- All patients with severe or moderate head injury require serial neurologic examinations while in the emergency department to allow early detection of herniation syndrome related to expanding traumatic mass lesions or increasing cerebral edema. A non-contrast CT scan should be performed on all moderate and severe head-injured patients.
- Acute herniation syndrome manifested by neurologic deterioration should initially be managed with short-term hyperventilation, to a Pco\(_2\) of 30 to 35 mm Hg, with monitoring and then surgical intervention as soon as possible. Long-term hyperventilation is not indicated. Mannitol or hypertonic saline should be used only in patients with increasing ICPs or acute neurologic deterioration.
- Secondary systemic insults such as hypoxia and hypotension worsen neurologic outcome after severe and moderate head trauma and should be corrected as soon as detected in the out-of-hospital or emergency department setting.
- For adult patients, hypotension in the presence of isolated severe head injury is a preterminal event. Hypotension usually results from comorbidity, and its cause should be sought and treated.
- The GCS is a useful clinical tool for following head-injured patients’ neurologic status, but because of its limitations, the initial GCS in the emergency department cannot reliably predict prognosis after acute head injury.
- Head-injured patients who have been chemically paralyzed do not have clinical manifestations of seizures; anticonvulsants should be given prophylactically.
- Most “talk and deteriorate” patients who present with moderate head injury have subdural or epidural hematomas. Early detection, CT scan, and expedient surgical intervention are the keys to a good outcome.
- Caution should be given to out-of-hospital RSI intubations in severe head injury if the intubations may be prolonged or significantly challenging. Alternative airway management should be considered.

### Minor Head Trauma

- Risk stratification of patients with minor head injury into low-risk and high-risk categories can help direct the emergency physician to an appropriate diagnostic workup.

---

### Key Concepts

- The decision to perform CT scans on patients with minor head trauma should be individualized but based on consideration of high- and moderate-risk criteria.
- Alcohol can affect the GCS and significantly obscure the neurologic examination. Intoxicated patients should be considered at high risk.
- Most patients with minor head trauma can be discharged from the emergency department after a period of observation but require a competent observer.
- Patients sustaining a concussion are at risk for prolonged and substantial morbidity. Athletes should not be allowed to return immediately to sports activities because of the potential risk of second impact syndrome. All current recommendations for return to play after a sports-related concussion state that players with concussion should not return to play for at least 1 week after they have become asymptomatic. This period is usually increased to at least a symptom-free month if an LOC or prolonged post-traumatic amnesia occurred at the time of concussion.

### Pediatric Head Injuries

- Children with severe head trauma have fewer intracranial lesions than adults but more edema. In children, increasing edema alone can cause talk and deteriorate or other significant neurologic decline.
- Skull fractures have more clinical significance in children than in adults.
- In children, unlike adults, hypovolemic hypotension can occur because of head injury, especially in those younger than 1 year of age.
- In very young children, head injury often occurs from nonaccidental causes. Child abuse should be suspected in young children with head trauma, especially those younger than 2 years of age.

### Penetrating Head Injuries

- Tangential gunshot wounds are associated with a high frequency of intracranial traumatic lesions; CT scanning should be performed.
- Anticonvulsant prophylaxis and antibiotics should be given to a patient with penetrating head injuries.
- The clinical outcome after gunshot wounds to the head can be predicted by the initial clinical presentation and the missile path through the brain.

CHAPTER 39  Facial Trauma

Mary Pat McKay and Ryanne J. Mayersak

PERSPECTIVE

This chapter discusses the epidemiology, diagnosis, and treatment of injuries to the skin, soft tissue, and bones of the face. A complex structure vital to the function of the person, the face comprises airway openings, entry to the gastrointestinal tract, and special sensory organs, including eyes, ears, and nose. Facial functioning is essential for eating, speaking, and effective nonverbal communication. The appearance and attractiveness of the face have significant implications for social interactions, sexual attraction, and self-esteem.

Apart from immediate threat to the patient’s airway and special sense organs, injuries to the face can have serious implications for the patient’s mental health and future functioning. In one study of predominantly unemployed young African American and Hispanic men, 25% had symptoms of posttraumatic stress disorder 1 month after being treated emergently for a midface fracture.

Although the emergency physician’s main goal must be to address life-threatening problems successfully, the care of facial injuries is aimed at optimizing the patient’s long-term appearance.

Four main specialties—ophthalmology, plastic surgery, otolaryngology, and oral and maxillofacial surgery—participate in the care of facial injuries. Among teaching hospitals, the specialties of plastic surgery, otolaryngology, and oral and maxillofacial surgery participate in approximately equal proportions. Among level 1 trauma centers, plastic and oral/maxillofacial surgeons predominate.

Early consultation with the appropriate specialist can expedite the care of facial injuries.

Epidemiology

In 2006, there were more than 29 million injury-related visits to U.S. emergency departments. Facial injuries accounted for a significant proportion of these visits and may result from either intentional violence (assaults and attempted suicide) or unintentional trauma (falls, sports, and motor vehicle crashes [MVCs]). Although MVCs used to be the most common cause of facial injuries, windshield improvements, increased use of safety belts, and the prevalence of air bags in vehicles are changing the epidemiology of facial trauma. Dual front-impact air bags have been required in all new vehicles since 1999, and safety belts are required for all passengers in the front row in 49 states (all except New Hampshire).

Seat belts and air bags significantly reduce the incidence and severity of facial injury in adults. Because they effectively prevent ejection, safety belts specifically avert the extensive scalp and facial degloving injuries associated with being ejected through the windshield.

Alcohol use by vehicle occupants decreases safety belt use and independently increases the risk of facial injury in MVCs. It also increases the risk of interpersonal violence. In one series, alcohol played a role in 49% of all maxillofacial fractures in patients requiring subspecialty care. Among those related to alcohol, 78% were due to interpersonal violence and 13% from MVCs. Interpersonal violence is increasingly cited as the cause of facial injury, particularly in inner-city populations. Falls, dog bites, some athletic activities, and flying debris are other common causes of facial injuries.

Because of the lack of external protection, facial injuries are common among riders of other motorized vehicles, particularly those who are not wearing helmets with face guards, including all-terrain vehicles (ATVs) and motorcycles. In one series in Alabama, 32% of injured ATV riders had a facial injury, and the presence of a facial injury was associated with increased overall injury severity. Among the youngest riders, facial injuries predominate: 31.1% of 0- to 5-year-olds injured while riding an ATV required emergency treatment for a facial injury in 2001 through 2003, although multiple safety and medical groups recommend no ATV use by people younger than age 16 years.

In motorcyclists, there is a significant association between facial injury and brain injury. Helmets reduce the risk of brain injury but may not protect against facial trauma unless they include a face guard.

Unfortunately, a separate group of the injured must now be considered: combat veterans. A review of injuries sustained in battle by combatants in Operation Iraqi Freedom and Operation Enduring Freedom and treated by U.S. military medical facilities for at least 72 hours revealed that 19% suffered injuries to the face, ears, or eyes. Nineteen percent of all these injuries were caused by gunshot, 79% by explosive device, and 2% by MVCs.

Among children younger than age 17 years, sports injuries account for 21% of facial and 29% of nasal fractures requiring specialist evaluation. Baseball and football helmets with face guards are successful at preventing childhood facial injuries, and their use should be encouraged by emergency physicians.

Children younger than age 6 years seem to be at significant risk for severe facial injuries from bites sustained from the family dog. Interactions between pet dogs and young children require careful supervision.
Facial injuries are a common acute presentation for victims of domestic violence. In one series, 81% of domestic violence victims presented with maxillofacial injuries, 30% of them with facial fractures. The location of the injury was consistent with the predominance of fist attacks; left-sided injuries predominated. Women presenting to the emergency department with facial injuries should be interviewed privately to allow an opportunity for disclosure and intervention for domestic violence.

Pediatric facial injury accounts for less than 10% of all facial trauma, and the face is the most common area of trauma in children suspected of being victims of abuse. However, the epidemiology of facial trauma among children reflects their physical development and behavioral patterns: toddlers learning to walk have a “falling zone” of trauma to the perioral region, nose, and forehead. Younger children are significantly more likely to have minor soft tissue injuries and to have been the recipient of a dog bite. Severe facial injuries in all pediatric age groups are more likely to be the result of an MVC or assault. Care should be taken by the emergency physician to correlate the child’s age and behavioral ability with the history of the injury and the physical findings. In particular, injuries to the lips or frenulum in a nonambulatory infant suggest “bottle jamming,” and bruises to the cheeks or neck are less common in falls. Although dental fractures in young children are relatively common, facial fractures before age 5 years are rare. If there is any question, the appropriate local authorities must be contacted.

Even in high-energy MVCs, appropriate use of child safety restraints protects against many facial injuries. The law in all 50 states requires the use of such restraints for children younger than age 4 years, and currently 42 states require booster seats until at least age 6 years and many beyond that age. For children younger than age 15 years who were involved in frontal crashes, those exposed to a deploying frontal impact airbag had a higher incidence of minor facial and chest injuries and severe upper extremity injuries, mostly related to being struck by the bag. As part of preventing facial trauma, parents should be encouraged to ensure that children younger than 12 years ride in the rear seat of the vehicle and all are properly restrained.

**PRINCIPLES OF DISEASE**

**Anatomy**

The face is a complex hollow space encapsulated by a bony structure overlaid with muscle and skin. It includes several special sensory organs: the eyes, ears, nose, and mouth.

**Bones**

The posterior portions of the face form the anterior wall of the calvaria, placing the face and its features in an intimate relationship with the structures of the central nervous system. The anterior facial skeleton is composed of the frontal bone, nasal bones, zygomas, maxillary bones, and mandible (Fig. 39-1). The sphenoid, ethmoid, lacrimal, vomer, and temporal bones lie deep within the facial structure, providing support and important sites for muscular attachments, including the muscles of mastication, speech, and deglutition. This musculature is innervated by cranial nerves IX and X.

**Nerve Supply**

The most anterior muscle layer includes the muscles of facial expression that are innervated by the seventh cranial nerve, which exists just inferior to the external auditory canal. The trigeminal nerve (cranial nerve V) supplies sensation to the face through three major divisions (I–III). The ophthalmic division (cranial nerve V1) supplies the upper third of the face, including the eye and the nose down to the tip. The maxillary division (cranial nerve V2) provides sensory innervation to the midface and includes the infraorbital nerve. The mandibular division (cranial nerve V3) supplies sensation to the lower third of the face.

**Ears**

The ears lie laterally along the sides of the face with the auditory canal exiting through the mastoid process of the temporal bone. The skeleton of the pinna is cartilage covered in closely apposed skin and rolled into a helical shape with a second ridge, the antihelix, defining the inner concha. The external auditory canal, middle ear, cochlea, semicircular canals, and superior origin of the eustachian tube all lie with the temporal bone.

**Eyes**

The structure of the globe and surrounding ocular musculature is discussed in detail in Chapter 69. The bony orbit is composed superiorly of the frontal bone. The zygoma forms the lateral wall and lateral floor of the orbit. The medial floor and anteromedial wall are formed by the maxilla. The lacrimal and ethmoid bones complete the medial wall, where the orbit is at its most delicate. The medial wall of the orbit forms the lateral walls of the intranasal space.

**Nose**

The nose serves as a major entryway for air and is composed of cartilage and bone covered by skin with mucosa lining the internal surface. Alar cartilage arches over the entrances to the symmetric, mucosa-lined nares, separated by the anterior cartilage of the septum. Superiorly, the nasal bones create the bridge of the nose. With the head held in a neutral upright position, the floor of the nose is perpendicular to the ground and leads back into the nasopharynx, passing the turbinates laterally and the bony septum medially. The ethmoid bone lies superiorly and crosses midline, behind the nasal bridge, to form the superior portion of the bony nasal septum and the cribiform plate. The vomer comprises the inferior portion of the bony septum, and the palatine process of the maxillary.
bone forms the posterior floor of the nose and the hard palate.

Air-containing sinuses are structural features unique to the facial skeleton. They serve to warm and humidify inhaled air and form chambers that create the unique tone of human voices. These sinuses develop over the period of human growth. At birth, only the ethmoid air cells and the mastoid antrum are aerated. The sphenoid sinus and the remainder of the mastoid air cells become aerated at approximately age 3 years. Frontal sinuses form at approximately age 6 years, and maxillary sinuses are not fully developed until age 10 years.

Mouth

The mouth serves as entry to the respiratory and gastrointestinal tracts. In addition, the fine motor movements of the mouth and tongue give humans the ability to communicate through speech. With the mouth in the closed position, the tongue fills the oral cavity. Single rows of teeth lie within the alveolar ridges of the maxilla and the mandible. With the mouth closed, the teeth in normal individuals occlude, with the lower row lying just internal to the upper row. The “usual” occlusion for individuals varies widely; the patient’s belief may be the best determinant of whether or not the teeth are meeting as usual. Anterior to the teeth is the vestibule, a fold of mucosa and flexible soft tissue that allows the lips to remain closed while various motor movements occur behind them. The mandible is a U-shaped bone that forms the chin and completes the lower facial skeleton. Containing the lower row of teeth, the body of the mandible meets in midline at the symphysis, which is completely fused by age 2 years. Posterior to the last molar, the bone turns to form the angle of the jaw and continues upward as the ramus of the mandible. At the most superior point of the ramus is the articular surface of the condyle, separated from the superior surface of the temporomandibular joint (TMJ) by an intervening meniscus of fibrocartilage. Anterior to the condyle lies a thin projection, the coronoid process, which provides the insertion point for the temporal muscle.

The skin of the face is among the thinnest of the body, draping over the underlying musculature. Facial skin falls visibly into predictable creases with age, following Langer’s lines (Fig. 39-2). At the mouth, nares, and palpebral fissures, the skin is contiguous with the mucosa lining these structures. The skin of the lips is particularly thin and lined with vascular papillae, which give the lips their vermillion hue. Lips are particularly important as part of communication; understanding their movement can allow language without sound (lip reading).

The face is a highly vascular structure; this can have grave implications for the treatment of facial injuries. With the exception of the ophthalmic artery, the superficial blood supply comes from the external carotid artery via the facial, superficial temporal, and maxillary arteries (Fig. 39-3). Soft tissue injuries and fractures that involve these vessels can lead to significant hematomas or exsanguinations. Because the face has extensive anastomotic connections across the midline and between arterial territories, however, ligation of major branches causes minimal ischemia.

Buried within the structure of the face are a series of glandular structures and ducts, which are susceptible to injury. In the eye, the lacrimal glands lie within the orbits, superior and lateral to the globes, and secrete tears through ductules into the folds of the conjunctiva. The liquid flows medially into the puncta of the lacrimal canaliculi and drains into the lacrimal sac and then via the nasolacrimal duct into the nasopharynx.

The salivary system consists of the parotid, sublingual, and submandibular glands. The parotid is the largest of these glands, lying just anterior to the ear and wrapping around the mandible. The parotid is superficial to the masseter muscle and drains via Stensen’s duct, a 5-cm tube that curves around the anterior edge of the masseter to enter the mouth opposite the second upper molar. In normal subjects, this duct is large enough to be palpated with the masseter clenched (Fig. 39-4). The sublingual glands lie entirely within the floor of the mouth and drain into the mouth via ductules. They surround the ducts draining the submandibular glands (Wharton’s ducts). The body of the submandibular gland is folded around the mylohyoid muscle so that a portion lies within the floor of the mouth and a portion lies external to it. The submandibular (Wharton’s) ducts run from the external portion of the gland to empty into the mouth on either side of the frenulum of the tongue.

Pathophysiology

The basic mechanism of all injury is the transfer of energy, most often kinetic, to the structures of the body. When the energy overcomes the tolerance of the underlying tissue, injury results. Trauma traditionally has been classified as blunt or penetrating, but in many cases the effect is a combination of the two, such as the forehead injury (contusion and complex laceration) resulting from a child’s fall against the sharp corner of a coffee table. The likelihood of injury is related to the amount of energy transferred and the condition of the underlying tissue. Significant injury may result when an 80-year-old falls from standing to a carpeted floor, but it is more likely to result when the face strikes the steering wheel or dashboard in a high-speed MVC.

The mechanism can be broken down into low-energy events, such as a fall from standing or walking into the corner of a
Understanding the mechanism of injury can not only help predict the severity of the facial injury but also predict the risk of associated cervical or brain injuries.

Traditional teaching has been that the face protects the brain from injury and that patients with facial trauma are less likely to have a significant brain injury. This does not appear to be correct. Instead, recent work suggests a significant increase in risk for brain injury among blunt trauma patients with facial fractures. The association between cervical injury and facial injury is unclear. The traditional teaching has been that the presence of a facial injury should increase the suspicion of an injury to the cervical spine. However, most of the studies supporting this idea are assessments of the incidence of cervical spine injury in patients with facial injury. When more sophisticated methods are used to assess any association between the two while correcting for the mechanism of injury, patients with facial injury appear to be less likely to have a significant cord injury, and there is no relationship with bony spinal injury. Thus, in a particular patient, cervical and brain injuries should be considered based on the mechanism of injury and presentation of the patient without allowing the presence or absence of a facial injury to change the level of suspicion.

Penetrating trauma to the face from gunshots, stab wounds, blast debris, or impalement is often obvious and dramatic. The astute emergency physician should search avidly for associated intracranial, spinal, or vascular injuries, which are common in these cases. Facial penetration from pellets (BBs) or small blast debris or shrapnel may be less obvious, and the emergency physician must be alert to the possibility based on the history and carefully search for small skin lesions. Unregulated guns created from plastic pipes and aerosol cans that shoot potatoes are used as toys in areas of the United States, mostly among adolescent boys. Significant facial trauma can result from these instruments, which can propel a potato 200 mph.
**Figure 39-5.** Impalement by a turn-signal lever. Computed tomography (A) and three-dimensional reconstruction (B) from a patient impaled through the face into the cranial cavity by the turn-signal lever from his steering column when his vehicle rolled over in a single-car crash. The color three-dimensional reconstruction reveals a significant injury to the facial artery (arrow).

### CLINICAL FEATURES

#### History

The history can provide information about the mechanism of the patient’s injury. The emergency physician should be alert to limitations of the history, however, when the patient’s consciousness is altered by head injury or intoxication, there is an issue of secondary gain, the police are involved, or abuse is suspected. Patients with a clear sensorium are able to describe the events leading up to the injury and localize pain; deficits in motor or sensory function; and abnormalities of vision, hearing, taste, or smell. Although the association between facial trauma and brain or cervical spine injury is unclear, these possibilities should be considered, and the patient should be questioned regarding headache, peripheral weakness, numbness, or paresthesias.

#### Physical Examination

Many facial injuries can be identified by simple inspection. During the primary assessment, attention is initially on the patient’s airway, and inspection of the oropharynx is an essential first step. Airway compromise is often due to intraoral trauma, and the examiner should note excessive bleeding, drooling, dysphonia, swelling of the tongue or posterior pharynx, and the presence of avulsed teeth. When the patient is stabilized, a secondary survey should include a systematic examination of all facial structures and functions. Bony prominences should be palpated for abnormal motion, bony crepitus, tenderness, or step-off. Tenderness and massive swelling associated with facial trauma may preclude reliable palpation of a fracture. Consequently, areas of significant swelling should be imaged radiographically. Assessment of bony integrity includes testing for possible Le Fort fracture. The upper incisors are grasped and pulled anteriorly. Movement of the upper alveolar ridge (type I), midface (type II), or entire face (type III) indicates a fracture. Wounds may need to be palpated for underlying bony injury or foreign objects; anesthesia may be required for a thorough examination within the wound. Complex lacerations involving the cartilage of the nose or ear, eyelids, lacrimal apparatus, eyebrows, or vermilion border of the lips should be identified because their repair requires special techniques.

#### Eyes and Orbits

In addition to looking at lacerations and contusions, the face should be evaluated for symmetry. The appearance of the zygomas may be evaluated by looking at the patient from above. This technique also draws attention to the relative position of the eyeballs. Orbital fractures may result in enophthalmos, and a large retrobulbar hematoma may cause exophthalmos. The anterior chamber of the globe should be inspected for hyphema or globe rupture. Hyphema is due to bleeding in the anterior chamber and appears as a layer of blood in the dependent portion of the anterior chamber. A complete examination of the eye requires specific testing. If the patient is able to cooperate, visual acuity should be documented. Contact lenses should be removed. In the event of a significant potential chemical exposure, the pH of the eye may need to be measured. Fluorescein examination of the eye should be performed if there is any concern about corneal abrasion. Victims of MVCs often have particles of glass in the conjunctiva or on the cornea, and these should be sought out and removed. Extraocular motions should be tested. Blow-out fractures of the orbit may result in diplopia on upward gaze secondary to entrapment of the inferior rectus muscle or anesthesia of the midface and upper lip in the distribution of second division of the fifth cranial nerve secondary to neuapraxia resulting from fracture through the infraorbital foramen or compression by a local hematoma.

#### Oropharynx

The integrity of the mouth and nasal complex may be evaluated by listening to the patient’s speech. A muffled or overly nasal voice may indicate occlusion of the nose or nasopharynx, whereas dysarthria may indicate a mandibular fracture, tongue injury, or neurologic problem. Oral injury may result in progressive airway compromise, and dysphonia should alert the clinician to the possible need for active airway management. The intraoral examination includes inspection of the palate, teeth, tongue, and gums and palpation with a gloved finger (the latter only if the patient is able to cooperate). The range of motion of the mandible should be determined. If the incisor opening is less than 5 cm, a mandibular fracture may be present. Trismus is likely to indicate a fracture or significant hematoma within the face. If awake, the patient’s
impression about the normalcy of bite occlusion is a more sensitive determinant of a fracture of the mandible than the physician’s impression. Being able to perform a tongue blade test (groping and holding a tongue blade between the teeth while the examiner pulls gently) is associated with greatly reduced probability of mandibular fracture. If the patient is able to crack the tongue blade by biting on both sides of the mouth, the negative predictive value for a mandibular fracture is 95%. Injury to the parotid area should raise suspicion of disruption of Stensen’s duct. The opening of the duct opposite the second upper molar should be examined for bleeding while the gland is compressed. If blood is expressed from the duct or the severed ends of the duct are identified within a facial wound, specialized repair over a stent is required to prevent formation of a cutaneous fistula.

Ears

Otoscopy is performed to evaluate the integrity of the external canal, look for hemotympanum, and assess for otorrhea. Clear fluid from the ear after trauma should raise the possibility of a cerebrospinal fluid (CSF) leak. At the bedside, a drop of the fluid may be placed onto filter paper. A rapidly advancing halo of clear fluid around red blood defines a positive test. This is a quick bedside test with good sensitivity (>95%) as long as the mix is approximately 50:50 between blood and other fluid, but it does not differentiate between CSF and saline, saliva, or other clear fluids.

The ear should be inspected for subcutaneous hematomas because these need to be drained.

Nose

The nose is palpated for tenderness, crepitus, or abnormal movement, and then each nare is held closed in turn to ensure the patient is able to breathe through either side. The septum should be examined visually to look for septal hematoma, which appears as a large purple mass extending from the septum. If there is any concern about CSF rhinorrhea, the aforementioned filter test may be performed.

Neurologic Examination

Light touch should be tested for all three branches of the fifth cranial nerve. Motor function (cranial nerve VII) can be examined by having the patient actively wrinkle the forehead, fully open and snug the eyelids shut, smile widely, and bare the teeth. Asymmetry of these movements indicates a potential nerve injury. Peripheral injuries to the seventh cranial nerve should have discernable weakness in the forehead as well as the orbital and oral musculature, whereas central injuries will have preserved forehead function because of crossing fibers distal in the course of the nerve.

The final part of the physical examination is documentation. Facial injuries may be evidence of assault, domestic violence, or child abuse. Careful documentation of findings, including photographs or drawings or both, not only communicates initial findings to other practitioners but also can provide crucial legal evidence because many of these cases have forensic implications or result in litigation.

DIAGNOSTIC STRATEGIES

Imaging

The choice of imaging for facial fractures depends on the patient’s stability, the patient’s ability to cooperate, and the availability of various options. The two main options are plain x-rays and computed tomography (CT). Fractures are better visualized on CT than magnetic resonance imaging, so magnetic resonance imaging is not an optimal imaging choice. In patients who cannot cooperate for plain x-rays or in whom a fracture or penetrating injury is obvious from the physical examination, CT is the imaging modality of choice. For a complete evaluation, CT scans of the face should include coronal and sagittal reconstructions. Interpreting facial CT scans is an art that requires attention to bones, sinuses, orbital contents, and soft tissue and is best handled by radiologists.

With the increasing use of CT in emergency medicine and the advent of telemedicine, most 24-hour emergency departments have access to CT scanners for facial injuries. CT is now the first choice for all patients in whom a midface fracture is suspected. However, when no scanner is available and in patients with low to moderate pretest probability of a midface or maxillary fracture and who are able to cooperate, the current recommendation is for a single screening view (a Water’s or occipitomental view), followed by CT if the film is positive for a fracture or air-fluid level in any sinus.

The U shape of the mandible and the presence of nearby bony structures make isolating the mandible on flat film impossible. Simple radiographs of the mandible are less sensitive than panorex radiographs and particularly tend to miss fractures of the condyle (Fig. 39-6). If available, panorex imaging is indicated for isolated mandibular fractures, dental fractures, or fractures of the alveolar ridge. In children, if fracture of the condyle is suspected, coronal CT is more sensitive and specific than panorex studies. Although the traditional teaching has been that the mandible’s shape mandates two fractures if it is fractured at all (Fig. 39-7), a case series using CT evaluation found that 42% of mandibular fractures were unifocal.

Figure 39-6. Panoramic radiograph of the mandible shows fractures through the left angle and the right body. A dental appliance is in place on the lower incisors.
For patients with complex fractures, new imaging techniques may help improve surgical planning and esthetic outcomes. In displaced orbital fractures, using CT data to measure orbital volumes has shown that after repair, an orbital volume greater than 4% larger than the unfractured side is associated with visible postoperative enophthalmos. This method seems to be useful in predicting which patients might benefit from operative repair. In conjunction with more standard two-dimensional facial CT scans, three-dimensional CT seems to improve the diagnosis and aid preoperative planning for patients with complex fractures of the midface (Fig. 39-8B).

Patients with tenderness and swelling isolated to the bony bridge of the nose who do not have a septal hematoma, can breathe through each nare, and have a straight nose do not require nasal bone x-rays in the emergency department because imaging results would not alter treatment. If these criteria are not met, early reduction or referral for surgical intervention may be indicated, and plain films (truly isolated injuries) or CT scanning (if concern for other injuries) is indicated. Plain x-rays may also be performed in the setting of legal concerns. If there is concern for a foreign body in a superficial wound, two standard x-ray views (Water’s and Caldwell’s or occipitofrontal view) are indicated to triangulate the position of the observed foreign material.

Patients with suspected ocular injuries may benefit from a bedside ultrasound as a noninvasive and economical diagnostic tool, particularly if there is a need for urgent operative management of other injuries and no time for a dedicated facial CT. The different acoustic impedances of the orbit’s anatomical structures make the modality operator friendly, and an ultrasound of the eye can readily detect vitreous hemorrhage, retinal detachment, and globe rupture (Fig. 39-9). Prior findings have suggested that high-resolution ultrasound has at least a 94% correlation with axial and coronal CT imaging in the detection of orbital fractures and emphysema.

**MANAGEMENT**

Management of facial injuries occurs within the overall resuscitation of the patient. Unless the airway is threatened or exsanguination is a concern, treatment of most facial injuries can be deferred until more life-threatening injuries have been stabilized. Care of the patient with penetrating trauma to the

---

**Figure 39-7.** Three-dimensional CT reconstructions of minimally displaced mandibular fractures in the same patient as in Figure 39-5.

**Figure 39-8.** Tripod fracture. Computed tomography (A) and three-dimensional reconstruction (B).
face should center on standard trauma care, with initial attention focused on maintaining a patent airway, adequate ventilation, and systemic perfusion.

**Out-of-Hospital Care**

The indications for airway management of a patient with a facial injury are the same as those for other patients: Does the patient have a currently patent airway, and if so, can the patient be expected to maintain it without intervention? If the answer to either question is “no,” the patient needs to be intubated. If other injuries preclude the patient from ventilating appropriately, intubation is also required.

Patients with expanding hematomas after facial injury present a special dilemma. Injuries to the facial vasculature may cause significant hematomas that can extend into the neck or down to the supraclavicular area. Such hematomas greatly distort the normal anatomy of the pharynx and neck, making intubation and cricothyroidotomy particularly difficult. If the patient has a patent airway, he or she can speak without difficulty, and the transport time is expected to be short, no intervention should be performed and the receiving institution should be notified so that planning can begin for a difficult airway. If intubation must occur in the field, awake orotracheal intubation should be considered. If certified in its use, emergency medical services personnel should be ready to perform a surgical airway as needed. Gunshot wounds to the lower third of the face to the lower third of the face are particularly likely to require intubation for airway protection, and a significant proportion of these require a surgical airway.

In the setting of significant facial trauma, active bleeding can obscure the view and make intubation considerably more difficult. Double suctioning may be required, which involves an assistant holding one suction catheter in the posterior oropharynx while the operator uses a second device more anteriorly or inferiorly as needed during the procedure. Conversely, patients with fractures of the mandible may be easier to intubate because increased mobility of the mandible may allow wider opening of the mouth.

Blind nasotracheal intubation is rarely indicated in facial trauma because of concerns about complications. Multiple-injured patients who require intubation may not be breathing actively enough for this method to be of use, and out-of-hospital rapid sequence intubation is associated with a higher success rate and fewer complications. Although reports of intracranial placement of an endotracheal tube in facial trauma are rare, this catastrophic complication is known to occur after blind nasotracheal intubation. Any concern about an injury to the skull base or cribriform plate is a contraindication to using this method of intubation.

Control of local bleeding is the other significant out-of-hospital consideration in facial trauma. In many areas, external compression is sufficient to control bleeding during transport. Epistaxis and significant intraoral bleeding can be more difficult to treat. Even in the setting of significant nasal trauma, the soft portions of the nares can be compressed to stop anterior nasal bleeding. In an awake, alert patient with intraoral bleeding, 4 × 4-inch gauze packing may be placed into the buccal space to provide control. If these maneuvers are insufficient and the patient’s injuries require spinal immobilization, intubation may be a necessary first step to control intraoral or nasopharyngeal bleeding. After intubation, large amounts of gauze can be placed via the mouth into the oropharynx and nasopharynx to obtain control via direct pressure.

If out-of-hospital personnel suspect a ruptured globe, special protection against compression of the eye (eye cup or noncontact shielding) should be provided in the field. Avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed parts, including ears, the tip of the nose, teeth, or completely avulsed
flaps, should be transported with the patient in saline-soaked gauze.

Completely avulsed teeth should be removed and carried with the patient during transport. Neurologically normal, unintoxicated patients may be able to carry avulsed teeth in their mouths, held between gum and buccal mucosa. Patients who are not neurologically normal, who are intoxicated, who require cervical spine immobilization, who are nauseated, or who cannot be transported upright should not be transported with avulsed teeth held in the mouth. In such cases, the risk of aspirating the teeth outweighs any other concerns and the teeth should be transported in a container with sterile saline. Incompletely avulsed teeth should be left in place and not manipulated.

**General Measures**

The initial evaluation in the emergency department should re-address the question of intubation. In the setting of significant distortion of the mouth, oropharynx, or upper neck by avulsion or hematoma, the awake fiberoptic method may optimize the chances of a successful intubation. When there is significant distortion of the oropharynx or larynx, a laryngeal mask airway may not achieve a sufficiently tight fit to allow ventilation. Emergent cricothyroidotomy is the procedure of choice if endotracheal intubation is impossible.

Unless there is life-threatening hemorrhage from the face, after the airway has been secured, facial injuries can be safely left to the secondary survey. The emergency physician should avoid being distracted by a facial injury and search intensively for head, neck, chest, abdominal, pelvic, and extremity injuries. In-depth ocular examinations and other special testing should not be performed until other serious injuries have been managed emergently.

Significant bleeding can often be controlled by compression. If compression fails, hemostasis can be achieved in the emergency department by ligation of the relevant vessel. Great care should be taken, however, not to clamp or tie structures blindly deep within the face because serious nerve or iatrogenic injury of ductal structures could result. Massive, uncontrollable bleeding from facial fractures occurs rarely and is best treated with arterial embolization, if available. Intravascular vasopressin has recently been suggested as an option for hemostasis.

In the rare case of a patient acutely exsanguinating from a facial wound, the external carotid artery can be emergently ligated. This ligation is best accomplished with surgical assistance.

Bite wounds, gross contamination, or significant tattooing from foreign bodies should be addressed definitively as soon as possible, given needs of the patient’s other injuries. Definitive treatment of simple soft tissue injuries can be left for 24 hours if needed after irrigation and temporary approximation. Ideally, facial fractures are treated early, before significant swelling occurs, or after several days when return of more normal facial contours can aid in the repair. The need for tetanus prophylaxis should be considered for all open wounds. If the injury is an animal bite, the need for rabies prophylaxis should be considered. Because the rabies virus is transmitted to the brain along nerve axons, and symptomatic disease theoretically may occur sooner with wounds of the head, face, and neck, initiating rabies treatment within 5 days of the injury is recommended.

Finally, because lead poisoning has been reported from the ingestion of shotgun pellets in patients with primarily facial injuries, consideration should be given to looking for the presence of pellets in the gastrointestinal tracts of these victims. A plain x-ray of the abdomen suffices. Early endoscopic removal of the pellets should limit future toxicity.

**Soft Tissue Injuries**

Soft tissue injuries to the face present an acute cosmetic concern for the patient. Areas may be contused, lacerated, abraded, or any combination of the three. When cleaned of any debris, abrasions may be covered in a thin layer of antibiotic ointment and left exposed or covered (as possible given their location). Patients with significant tattooing benefit from topical lidocaine for anesthesia before vigorous scrubbing necessary to remove the embedded material is begun. Careful attention should be placed on removing all of the embedded material as soon as possible because epithelialization requires the creation of a new wound to remove debris later. For contusions, ice and sleeping with the head elevated may limit the degree of swelling anticipated on days 2 and 3. The patient should be cautioned to anticipate the development of peri-orbital swelling or ecchymosis or both over time as a result of gravity when the primary contusion has been to the brow, forehead, or bridge of the nose.

The most appropriate person to close an open wound may be the emergency physician or a consultant. Decisions about which wounds to close personally and which to ask a consultant to repair are based on the personal judgment of the emergency physician. Factors that may be considered in the decision include resource availability; the size, shape, depth, and location of the wound; and the time commitment that careful, cosmetic wound closure can entail for the emergency physician in a busy emergency department. The patient’s priority with facial lacerations is cosmesis, and as such a patient may request specialty services for even minor wounds. Children and patients with behavioral problems may require sedation to allow sufficient control for a cosmetic repair. Repair of facial wounds in uncooperative patients who are acutely intoxicated may be delayed until they become sober enough to cooperate for the procedure.

After anesthesia is obtained, wounds should be explored for depth, foreign bodies, or underlying fractures. Irrigation may not be necessary in simple, clean facial wounds closed within 6 hours. For nongaping wounds less than 3 cm, a single-layer closure may be sufficient. For gaping wounds deeper than the dermis, subcuticular buried sutures using absorbable materials should be placed to close any potential space and relieve any tension on the skin. For skin closure, tissue adhesive is faster and less painful, results in equal cosmetic results in adults and children, and can be used to close the skin over deeper sutures. Compared with sutures, tissue adhesive has the additional benefit of not requiring later removal, but care must be taken not to unintentionally glue the eye, nares, or mouth closed.

Antibiotics are not required for simple facial wounds, which rarely become infected. Bite wounds, wounds with any evidence of devascularization, wounds through and through the buccal mucosa, wounds involving the cartilage of the ear or nose, and wounds with extensive contamination (particularly with barnyard or fecal matter) are exceptions to this rule.

The choice of antibiotic therapy will likely be an evolving topic in light of the emergence of community-associated methicillin-resistant *Staphylococcus Aureus* (CA-MRSA). Among spontaneous skin infections requiring an emergency department visit, the prevalence of CA-MRSA is now quite significant for both adults and children. In addition, it appears that the incidence of such spontaneous infections requiring emergency department care is also increasing. However, current literature does not suggest choosing antibiotics with
PART 2 Trauma / Section Two * System Injuries

332

MRSA coverage for wound prophylaxis. If prophylactic antibiotic therapy is needed, the antibiotic should be selected based on the normal bacterial flora associated with the affected site.79

SPECIAL CONSIDERATIONS BY SITE

Mouth

Lacerations

Lip lacerations are common and require special consideration to maintain the appearance of the lip edge or vermilion border and the natural architecture of the philtrum. Because infiltration of even a small volume of local anesthetic may distort and blanch the soft tissue, marking the vermilion border (with nonpermanent ink or a scratch of a sterile needle) before anesthesia facilitates a cosmetic repair. To minimize any divots and maximize cosmesis and function, wounds that include the muscular layer should be closed in multiple layers. Skin may be closed with nylon or other nonabsorbable suture; the lip and mucosa should be closed with absorbable suture. Lip lacerations are not amenable to closure with wound adhesives.

Through-and-through lacerations of the mouth should be closed in layers, beginning with the intraoral mucosa and working outward in layers toward the skin. Following closure of the mucosal layer, copious irrigation of the external wound is indicated to remove lingering bacteria that otherwise would be incorporated into the wound. In small case series, prophylactic treatment with penicillin has been shown to decrease the risk of infection after significant through-and-through lacerations.80 Lacerations that approach the parotid (Stensen's) or submandibular (Wharton’s) ducts should be evaluated before intervention for ductal integrity. Saliva milked from the gland should be thin and clear and readily exit the duct. If a duct is involved or there is any doubt, a facial specialist should be consulted for evaluation and repair.

Small lacerations of the tongue or oral mucosa do not require repair. Lacerations that gape (including deep tongue lacerations) collect food and are likely to heal with a significant divot or thick scar that may hinder eating and speaking functions require repair. Deep or gaping lacerations of the tongue or oral mucosa should be closed (in layers if necessary) using absorbable sutures that do not require removal. To facilitate repair, an assistant may be needed to expose the laceration by grasping the tongue between gauze and holding a segment outside the mouth. Some advocate placing a thick temporary suture through the distal tongue (after appropriate anesthesia) to facilitate this exposure. Discharge instructions for intraoral lacerations (whether or not repaired) should include gentle cleansing (swish and spit) with a mild antiseptic.

Nose

Contusions of the cheek should raise concern for an underlying zygomatic or maxillary fracture. Lacerations of the lateral cheek may involve the parotid gland or Stensen’s duct. Failure to identify and repair ductal injury results in retention of salivary fluid and enlargement of the gland or formation of a cutaneous fistula. Lacerations in the area anterior to the tragus may involve injury to the facial nerve, and careful neurologic examination should be carried out before closure. Langer’s lines change from mostly horizontal in the superior cheek to diagonal at the nasolabial fold, then curve convexly around the mouth; these changes should be taken into consideration when débridement is required as part of a complex repair.

Perioral Burns

Young children use their mouths to explore their environment and may lick electrical outlets or bite electrical cords. The wet oral mucosa provides little electrical resistance, and the current penetrates to deeper structures, often causing a full-thickness burn at the commissure of the lip. These children need a systemic evaluation for other electrical injury (see Chapter 140); this discussion is limited to the evaluation and treatment of facial wounds. Perioral burns resulting from electrical injury can result in severe cosmetic problems and microstomia. The initial appearance of the wound may be misleadingly trivial; edema and necrosis progress over several days, and even with healing, the defect may become quite disfiguring. Traditionally, a more acute concern has been bleeding from the labial artery when the maturing burn eschar separates from underlying structures 5 to 21 days postburn, and it was previously recommended that patients be admitted so that such bleeding could be urgently addressed if it occurred. Generally, current practice is discharge with close observation at home and follow-up with otolaryngology and/or plastic surgery to address cosmesis. Large wounds can cause significant early difficulty with eating, however, and patients may require placement of a nasogastric tube for maintenance of nutrition. Initial emergency department treatment of the wound is aimed at treating discomfort and keeping the area clean.

Treatment of these injuries is controversial; options include conservative treatment with early oral splinting, immediate surgery aimed at reconstruction, or delayed excision of the burned area. Later reconstructive repair may be required to preserve mouth opening, eating, and speech clarity.81 Early involvement of consultants is indicated, even when the burn seems to be trivial. The possibility of abuse or neglect should be considered when a child presents with a perioral burn.

Cheeks

Because of its anterior position, soft tissue injuries to the nose are common. Almost any trauma can result in epistaxis. Generally, epistaxis is controllable by pinching the cartilaginous anterior nose closed between two fingers and holding compression for approximately 10 minutes. If not, anterior packing is indicated. Intranasal inspection is required in any nasal injury to assess for a septal hematoma, which appears as a dark purple or bluish mass against the septum. Hematomas require drainage because they are associated with necrosis of the septum if left untreated. Simple incision and expression of the clot followed by anterior packing is sufficient. Traditional teaching has been that any patient with nasal packing should receive prophylactic antibiotics to cover Staphylococcus and Streptococcus species in order to prevent sinusitis and toxic shock syndrome. Toxic shock syndrome is a rare but measurable complication of postoperative nasal packing, occurring in approximately 16/100,000 cases; the incidence with primary packing is unknown.82

There is no evidence whether prophylactic antibiotics change the risk of developing toxic shock syndrome or sinusitis in postoperative or primary packing; the few studies that have been done have had sample sizes far too small to show an effect.

Because of its location and structure, fractures of the thin bones of the nasal bridge are common. Patients with contusion or tenderness over the bridge of the nose may be assumed to have fracture of the nasal bones. If the nose is acceptably straight on initial evaluation, there is no septal hematoma, epistaxis is controlled, and the patient is able to breathe out
of each nare, no further evaluation is required emergently for isolated nasal injuries. Although still in use, there is no clinical utility to radiographs of the nasal bones.83-85

Swelling over the bridge often precludes determination of the acceptability of the appearance at the time of injury. The patient may be provided with a referral for outpatient specialty follow-up in 3 to 5 days if the appearance at that time (when the swelling has improved) is unacceptable. In a series of surgically repaired simple nasal bone fractures, septal fractures were present in more than 50% of cases. CT did not provide any advantage in diagnosing septal fracture and should be reserved for evaluating patients suspected of having other, more complex fractures.86

Children with nasal fractures may have premature closure of sutures or uneven growth, particularly of the vomeroseptal line. In a child, no imaging studies are indicated, but a consultant should evaluate swelling and tenderness over the nose, preferably within 4 days of the injury.87

Simple lacerations of the nasal skin may be closed with sutures or tissue adhesive. If needed, anesthesia may be obtained using a nerve block of the infraorbital or supratrochlear nerves. The large pores typically present in the area of the nasal ala increase the likelihood of stitch abscesses after laceration closure in this area. Closure using an absorbable running subcuticular suture may limit the risk of this outcome. If involved, the cartilaginous portions of the ala should be closed in a separate layer. For lacerations through and through the nose, repair should be carried out from the mucosal layer outward, with copious irrigation between layers.

Ears

Blunt trauma to the ear may cause hematoma formation in the subperiosteal potential space. Such hematomas are the prelude to the development of a “cauliflower ear” and should be drained by aspiration. Recumulation of the hematoma is prevented with a compressive dressing of the ear, but reexamination is crucial, and reaspiration should be performed as necessary.

Ear lacerations often involve the cartilage. The ear may be anesthetized using a field block: 1% lidocaine without epinephrine is injected subcutaneously into the skin around the base of the ear. Simple skin wounds may be closed in a single layer. Lacerations to the underlying cartilage should be repaired using absorbable material. If there is significant degloving or loss of overlying tissue, a consultant should be involved; portions of aural cartilage may be saved temporarily in a distant dermal pocket for later reconstruction. Because cartilage is avascular, chondritis, when it occurs, requires extensive débridement and is disfiguring. No randomized trials have been performed, but when the cartilage of the pinna requires repair, antibiotic prophylaxis is recommended. Compressive ear dressings (splints) are indicated after any significant repair. Ear injuries occurring before age 1 year or injuries to both ears in children are rare and should raise the suspicion of abuse.88

Eyes

Simple eyelid lacerations may be repaired in a single layer. Wound adhesives should be used with great caution anywhere near the eye; care must be taken not to glue the eyelids open or shut. Lacerations that involve deeper structures, loss of tissue, or the lid margin should be referred to a consultant. The integrity of the lacrimal apparatus can be assessed by instilling fluorescein into the eye and assessing for dye in the wound. A consultant should handle any injury to the sac or lacrimal duct.

Eyebrow lacerations are common because of the overhanging supraorbital ridge. Careful wound exploration should be performed to assess the integrity of the underlying bony structure. No shaving should be performed because the brow hairs may not regrow, and the hairs are necessary for realignment. If débridement is required, it should be done parallel to the hair follicles (skived) rather than perpendicular to the skin. This approach minimizes the bald area of the scar. Closing the deeper muscular layers preserves the normal expressive function of the brow. Injuries to the globe are discussed in Chapter 69.

FRACTURES AND DISLOCATIONS

For the emergency physician, the key to facial fractures is accurate diagnosis and appropriate referral. Many nondisplaced or minimally displaced facial fractures may be handled on an outpatient basis, with definitive repair or fixation delayed several days. Adult fractures develop firm fibrous union within approximately 10 to 14 days; however, definitive repair is performed most easily before day 7. Methods for diagnosing fractures were discussed previously. Fractures to the face of young children are relatively rare and may be incomplete or greenstick fractures. Fibrous union in these cases is rapid; early reduction (within 3 days) is recommended.

Antibiotics are indicated for open fractures and fractures that violate a sinus. Patients with fractures through the nasoethmoid complex that violate the maxillary bones or the floor of the orbit should be cautioned to avoid sneezing and blowing the nose because these activities force air out into the soft tissues of the face.

Surgical repair of simple nasal fractures may be performed closed and the nose splinted internally or packed. Repair of fractures of the floor of the orbit, when necessary, may require the placement of a silicone patch to occlude the opening into the maxillary sinus. Most other fractures of the face that require operative repair are performed using small metal plates (microplates), screws, or wires to stabilize fragments by attaching them to unbroken segments of bone. Efforts are made to return the features to their unfactured locations and to regain facial symmetry, if possible. Complex facial fractures may have to be repaired in a staged fashion, depending on the patient’s degree of illness and the amount and quality of the bone remaining. Much of this surgery is best accomplished when the fragments are still freely mobile, but initial swelling has been reduced, on postinjury days 3 to 5.

Specific Considerations by Site

Forehead

Fractures through the superior forehead may occur above the level of the frontal sinus. These are actually skull fractures rather than facial fractures and should be addressed with special attention to risk of injury to the underlying brain. Unlike other skull fractures, frontal skull fractures often require repair for cosmesis alone. More often, fractures in this area involve the anterior portion of the frontal sinus. If even minimally displaced, these fractures require elevation for cosmesis. Fractures through the anterior wall of the frontal sinus are likely to continue through the posterior wall, and a CT scan should be performed to look carefully for this complication; if present, a CSF leak should be assumed until proved otherwise. CSF leaks into the frontal sinus may also present in a delayed manner, days or years after the initial injury.89 Many frontal sinus fractures require complex repair or obliteration to treat this complication.90
The most common simple fracture of the orbit is blow-out fracture of the orbital floor, often caused by a fist to the cheek or ball striking the globe, increasing intraorbital pressure enough to force orbital contents through the floor. This injury may happen without other significant bony facial injury. When displaced, the bony fragments sag into the underlying maxillary sinus. If the inferior rectus muscle is entrapped in the defect, the patient is unable to elevate the globe on the affected side, resulting in diplopia on upward gaze. Stretch on the infraorbital nerve, which passes through the floor, may cause anesthesia over the anteromedial cheek and upper lip. Because signs of entrapment may result from contusion and edema and be self-limited, immediate repair is not necessary, but careful follow-up is required. Repair typically is performed 1 to 2 weeks after the injury for persistent enophthalmos or diplopia. Because of the acute limitation in the visual field, discharge instructions for patients with acute diplopia should include patching for comfort and a request not to drive until the diplopia is resolved.

Fractures of the medial orbital wall, through the lamina papyracea, are often associated with nasal injury or more general midface fractures, particularly with telescoping of the midfacial skeleton. Herniation of orbital contents into the ethmoids may occur. In one study, patients with orbital fractures with a medial component were more likely to have ocular signs of diplopia or exophthalmos than patients with fractures that did not involve the medial wall. Fractures involving the superior orbit include the base of the frontal sinus, and all of the concerns about the anterior skull mentioned previously apply. Herniation of orbital structures into the frontal sinus is rare but can occur.

Many orbital fractures involve more than one wall of the orbit and may present in a constellation with complex midface fractures (Fig. 39-10). Several classification schemes aimed at improving communication among emergency physicians, radiologists, and maxillofacial surgeons have been proposed, but no classification system is generally accepted.

Figure 39-10. Computed tomography shows fractures of the left orbital floor and left lateral maxillary wall. There is streak artifact from dental devices.

Injury to the orbit, particularly fractures, can cause a hematoma to form within the orbit, behind the globe. If significant in size, a retro-orbital hematoma can cause acute exophthalmos. Stretch on the retinal artery limiting flow to the retina or neurapraxia of the retinal nerve may cause decreased visual acuity or blindness. Orbital emphysema associated with fractures of the medial wall or floor rarely results in a space-filling lesion with the same effect. This is a true emergency; drainage of the air or blood via lateral canthotomy with cantholysis is indicated to save the patient’s vision. Needle aspiration of entrapped air may also be attempted, but this may be best left to a consultant given the proximity of the globe.

Midface

Tripod (or trimalar) fractures are among the simplest fractures of the midface and include fractures of three bones: the lateral orbit, the zygoma, and the maxilla (Fig. 39-10). Typically caused by a direct blow, these fractures are often displaced and require operative stabilization. If left untreated, the area may “sink” posteriorly and inferiorly, giving an unacceptable appearance of facial asymmetry emphasized by the inferior position of the orbit and malar flattening. On the initial physical examination, there may be a large contusion over the cheekbone, enophthalmos, or malocclusion of the upper teeth. Fractures through the anterior wall of the maxillary sinus may denervate the maxillary teeth because the dentoalveolar nerves run in tunnels in this area.

More complex fractures of the midface are classified using the Le Fort system, although many complex fractures defy classification with this system. A Le Fort I fracture involves a transverse fracture through the maxilla above the roots of the teeth and may be unilateral or bilateral. Patients may complain of malocclusion, and the maxilla may be mobile when the upper teeth are grasped and rocked. A Le Fort II fracture is typically bilateral and pyramidal in shape. It extends superiorly in the midface to include the fracture of the nasal bridge, maxilla, lacrimal bones, orbital floor, and rim. In these cases, the nasal complex moves as a unit with the maxilla when the teeth are grasped and rocked. In the current age of CT scans, in which the full extent of comminution can be appreciated, simple Le Fort III fractures are rare but essentially involve fracturing of the connections between the elements of the skull and the face (craniofacial dysjunction). These fractures start at the bridge of the nose and extend posteriorly along the medial wall of the orbit (ethmoids), along the floor of the orbit (maxilla) and through the lateral orbital wall, and finally break through the zygomatic arch. Intranasally, they extend through all the lesser bones to the base of the sphenoid and frequently are associated with a CSF leak.

Significant force to the bridge of the nose may fracture the deep nasoethmoid complex without creating a formal Le Fort pattern. CT is the initial test of choice in this setting. Fractures to the central portion of the ethmoid bone (cribriform plate) are likely to be associated with a CSF leak and commonly result in anosmia.

If possible, patients with a CSF leak should have the head elevated 40 to 60 degrees. Head elevation minimizes the intracranial pressure, with the idea of decreasing the flow and allowing the leak to seal. Often, these patients are treated with antibiotics; however, this practice is controversial, and most of the studies supporting it involve small, local case series. In one meta-analysis, antibiotics did not decrease the rate of meningitis in the setting of CSF leak. Neurosurgeons should be involved in the care of patients with CSF leaks, although many leaks will spontaneously resolve.
Fractures involving the deeper structures of the midface may be associated with significant bleeding into the nose or oropharynx. Anterior nasal packing may be performed safely in the adult patient with multiple trauma. Even a 10-cm anterior pack should not reach the skull base in a skeletally mature person. Significant or massive bleeding into the posterior nasopharynx presents a complex problem and occurs in less than 1% of patients with midface fractures. It may be treated with nasal packing and immediate fracture reduction. Unless the anatomy is well understood and the skull base known to be intact, the use of a long balloon catheter (Foley) should be avoided for control of posterior bleeding. The unintended positioning of these items within the intracranial or intraspinal space during blind nasal insertion has been well documented, and when the face is grossly distorted, preinsertion measuring or other methods of preventing this outcome have not been adequately tested. There are no reports of the intracranial placement of commercial catheters designed for posterior epistaxis, but if the midface is significantly distorted or telescoped, they may be long enough to reach the intracranial space. An alternative method for containing posterior nasal bleeding is to provide compression by packing the area with gauze by hand from the oropharynx after intubation.

Zygoma

Isolated fractures of the zygoma are relatively rare, usually the result of a direct blow, and are often displaced. Because the condyle of the mandible may disturb zygomatic fragments while moving, fractures with significant displacement are likely to result in trismus or discomfort with mouth opening. Surgical repair is usually required to return the cheekbone to an acceptable position.

Mandible

Fractures of the mandible can result from any significant force applied to its U shape. Because of its shape, multiple fractures may result from a single blow, and the fracture sites may be distant from the site of impact. Depending on the location of the fractures, the patient may have trismus (fractures of the coronoid process, neck, or rami), dental malocclusion, swelling, and tenderness intraorally or externally. Anesthesia of the lower lip may occur if there is damage to the inferior dental nerve.

Fractures of the symphysis, body, angle, or rami usually require early splinting, typically by the placement of arch bars to accomplish interdental fixation, commonly known as “wiring the jaw shut.” Fixation limits fracture motion, decreases the patient’s discomfort, and, if the fracture is minimally displaced, may provide complete fracture care. Impacted and nondisplaced fractures occasionally are treated with only a soft diet, and fractures of the coronoid alone usually require no intervention, but these decisions should be made in consultation with an oral surgeon or other specialist. Arch bars may be placed in the emergency department or operating room and typically are placed by a specialist (see Fig. 39-6). Fracture reduction may require the extraction of teeth adjacent to the fracture line. Patients with open fractures require antibiotics and usually hospitalization. When the fractures are closed and adequate stabilization can be obtained, elective operative repair can be performed as an outpatient procedure in 3 to 5 days.

In one study, 17 to 22% of pediatric patients 4 to 11 years old developed facial growth disturbances after a fractured mandible and required later orthognathic surgery for correction. Children younger than 4 or older than 11 years were much less likely to develop this complication. Because of the frequency of this complication, children in this age group with a blow to the chin and any trismus or tenderness over the TMJ should be assessed carefully with panoramic imaging for condylar fracture and referred appropriately.

Dental and Alveolar Trauma

Trauma to the teeth may occur with or without other facial injury. In the setting of caries, tooth fractures may occur with eating relatively soft foods. Tooth fractures are classified by the Ellis system. Class I fractures involve only the enamel of the tooth, are not painful, and can await dental evaluation as an outpatient. Class II fractures expose the yellow dentin and may be painful. These also can await dental care, but they may be covered with a dressing of calcium hydroxide and aluminum foil. Class III fractures expose the dental pulp, seen as a red line or dot, and are exquisitely painful. These require early evaluation by dentists or endodontists.

Sufficient energy to the area avulses teeth from their sockets. Multitrauma patients, particularly patients who are intoxicated, required to be supine for cervical spine immobilization, or neurologically impaired, should have avulsed or mostly avulsed teeth removed from the mouth and placed externally in saline as an aspiration precaution. In a critically ill multitrauma patient, avulsed teeth should be among the lowest priorities and replanted only if the care of other injuries would allow it and there is no risk of aspiration if the teeth loosen.

To perform a reimplantation, the physician disturbs the socket as little as possible, gently rinses off the tooth (the root should not be wiped), and places it into the socket where it “clicks” into place. If the tooth is only partially avulsed, extruded, or laterally luxated, it should not be removed; it should be reimplanted or relocated. Intruded teeth should not be manipulated. Reimplantation can be painful and may require local anesthesia with a regional dental block. Alternatively, the area of a single socket may be anesthetized by placing approximately 0.5 mL of 1% lidocaine without epinephrine into the buccal sulcus and gum on the outer side of the alveolar ridge. After reimplantation, the tooth requires stabilization with acrylic splint or wiring to the adjacent teeth.

Replaced teeth may or may not “take” acutely, but it can take weeks to assess the final success of reimplantation. The length of time out of the socket seems to play a critical role in the initial success. Among teeth successfully reimplanted in less than 1 hour, more than 66% were radiographically healed and functionally normal after 5 years. For teeth successfully reimplanted after 3 hours, more than 80% had signs of inflammation and bone resorption after the same period of time.

In children, the front maxillary incisors are most commonly avulsed. After reimplantation, these teeth may ankylose and fail to “grow out” normally, requiring later extraction or orthodontic intervention for cosmesis. This situation is most common among children age 6 to 10 years with avulsed adult teeth.

Avulsed teeth missing after significant trauma should be carefully sought, including obtaining a chest x-ray. In an acute event, the patient may not recall aspirating a tooth; this is more likely if the patient is intoxicated or neurologically impaired. If the tooth is below the diaphragm on the film, it does not require retrieval. Teeth lodged in a bronchus or the esophagus require bronchoscopic or endoscopic retrieval. Aspirated teeth result in pulmonary abscess formation unless removed.

Fractures through the alveolar ridge may result in a group of teeth being dislodged and out of position, often leaning inward. These teeth require stabilization with wire or acrylic splinting after fracture reduction returns the teeth to their
correct location. The involved teeth may or may not survive after such a fracture, and careful follow-up with a dentist or oral surgeon is required.

**Temporomandibular Joint**

The TMJ is complex, with the condyle of the mandible undergoing rotation and translation anteriorly during normal mouth opening. The function of the joint is preserved by a meniscus, which overlies the condyle. Essentially, the joint between the meniscus and the condyle is a hinged joint, allowing rotation, and the joint between the meniscus and the temporal bone is a sliding joint, allowing translation. A formal, thick joint capsule does not exist at the anteromedial portion of the joint; loose, relatively weak synovial tissue is positioned here to allow translation to occur.

Trauma to the TMJ may tear the meniscus or injure the collateral ligaments holding it in a normal position. This injury can cause the meniscus to fail to translate normally, resulting in clicking or popping as it catches up to the condyle or inability to open the mouth fully because the meniscus completely fails to translate. Patients without fracture but with acute pain and difficulty with mouth opening should be placed on soft foods, asked not to yawn or struggle to open their mouths widely, and referred to an oral surgeon with expertise in TMJ pathology. Pediatric patients with posttraumatic internal derangements of the TMJ are prone to asymmetry of facial growth and retrognathia. In one study, 88% of children injured before their ninth birthday had significant facial abnormalities years later.105

Because of the anatomy and function of the joint, anterior dislocation of the TMJ can occur after widely yawning, laughing, kissing, singing, or other activities that involve spontaneous, wide opening of the mouth. When the condyle is out, spasm of the muscles of mastication prevents spontaneous reduction. Significant trauma is more likely to cause a fracture-dislocation. Simple dislocation may be unilateral or bilateral, and the patient complains of being unable to close the mouth. In unilateral dislocation, the jaw is rotated laterally away from the affected joint; bilateral dislocation causes significant protrusion of the jaw. The jaws of these patients are often so widely open that they cannot swallow their secretions and are actively drooling. Speech is often garbled by the patient's inability to touch the tongue to the roof of the mouth or the maxillary teeth. There is a depression in the area of the affected TMJ on inspection of the patient's face.

If the mechanism of injury suggests a fracture, the area should be imaged with plain x-ray or panorex before attempting reduction. To reduce a simple dislocation, the patient should be seated upright. To maximize leverage, the best position may be for the patient to be seated in a regular chair with the operator standing in front of the patient. As in dislocations of other joints, adequate analgesia and sedation are required for success. Using the thumb or index finger placed into the buccal sulcus on either side of the mouth, the angle of the jaw is pressed downward while rotating the symphysis (chin) upward and backward. Care should be taken not to place fingers along the crowns of the teeth; when relocation occurs, spasm of the muscles of mastication snaps the mouth shut with force. If this is the only location possible for the physician's fingers, gauze wrappings should be placed to protect them.

Panorex or x-rays are suggested after the first episode of dislocation. Patients with fracture dislocation are predisposed to a recurrence. In patients who are frequently dislocating, interdental fixation may be required for 2 or 3 weeks.

**DISPOSITION**

The decision to discharge or admit patients with facial trauma depends on their associated injuries, general injury severity, and plans for treatment. Patients with isolated facial trauma that has been repaired or stabilized and with no airway issues are usually discharged.

---

**KEY CONCEPTS**

- The face is central to the patient's ability to breathe, eat, and communicate. Injuries to the face can have serious psychological and psychosocial consequences.
- Facial injuries may be prevented by the appropriate use of safety belts, child restraints, air bags, helmets, and mouth and face guards.
- The epidemiology of facial injury is changing, with an increasing proportion occurring as a result of interpersonal violence. A careful history is required, and the possibility of abuse should be considered for every patient.
- Shock is rare from facial trauma and results only from obvious external bleeding. Facial injuries should not distract the emergency physician from aggressively searching for other causes of shock.
- Assertive management of the airway is indicated in a patient with significant facial injuries. Surgical management (cricothyroidotomy) may be required, particularly with gunshot wounds.
- Directed facial CT scanning is the best imaging technique in patients with obvious injuries.
- Definitive treatment may be delayed if needed to allow other serious injuries to be addressed.

Perspective

Background
Prehistoric humans undoubtedly suffered little in the way of significant spinal injury. Their semierect posture combined with well-developed posterior cervical muscles protected the cervical spine against day-to-day trauma. Evolution, however, did much to undo this initial protective state. As humans assumed an upright posture, the shoulders dropped away from the newly elevated head and the hypertrophied paraspinous muscles atrophied. This increased the head’s range of motion but diminished the spine’s protection. Although civilization heightened man’s inventiveness, it unfortunately did little to curb his aggressiveness. Automobiles replaced horse-drawn carriages, and fists and clubs gave way to knives and guns, making spinal injuries more common in the modern era.

Epidemiology
Statistics from the National Spinal Cord Injury Database show that motor vehicle collisions (MVCs) account for almost half of all spinal injuries. Speeding, alcohol intoxication, and failure to use restraints are major risk factors. The next most common cause of spinal cord injury (SCI) is falls, followed by acts of violence (primarily gunshot wounds) and sporting activities. There are currently more than 250,000 spinal injury victims living in the United States, and 11,000 new cases occur each year. Approximately 80% of victims are male, and the average age at injury is 38 years. The lifetime cost to care for SCI victims ranges from $500,000 for people older than 50 years with incomplete motor function to $3 million for people younger than 25 years with complete paraplegia. The total cost to society from life-long medical expenses and lost productivity is estimated to be more than $5 billion. The devastating emotional and psychological impact on the victims and their families is incalculable.

Principles of Disease

Anatomy and Physiology
The human spine consists of 33 bony vertebrae: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral (fused into one), and 4 coccygeal (usually fused into one) (Fig. 40-1). These 26 individual units are separated from one another by flexible intervertebral disks and connected to form a single functioning unit by a complex network of ligaments. In addition to providing basic structural support, the vertebral column protects the spinal cord, which extends from the midbrain to the level of the second lumbar vertebra. Nerves that receive and transmit sensory, motor, and autonomic impulses pass to and from the spinal cord through intervertebral foramina.

To assess the stability of spinal injuries below C2, it is helpful to view the spine as consisting of two columns. The anterior column is formed by alternating vertebral bodies and intervertebral disks held in alignment by the anterior and posterior longitudinal ligaments (Fig. 40-2A). The posterior column, which contains the spinal canal, is formed by the pedicles, transverse processes, articulating facets, laminae, and spinous processes. It is held in alignment by the nuchal ligament complex (supraspinous, interspinous, and infraspinous ligaments), the capsular ligaments, and the ligamentum flavum (see Fig. 40-2B). If both columns are disrupted, the spine will move as two separate pieces, and there is a high likelihood of that movement causing or worsening an SCI. In contrast, if only one column is disrupted, the other column resists further movement, and the likelihood of an SCI occurring is much less and depends on the strength of the intact ligaments.

Pathophysiology
Classification of Spinal Column Injuries
Acute spinal injuries are classified according to the mechanism of trauma: flexion, flexion-rotation, extension, and vertical compression (Table 40-1).

Flexion. Pure flexion injuries involving the C1-C2 complex can cause unstable atlanto-occipital or atlantoaxial joint dislocation, with or without an associated fracture of the odontoid (Fig. 40-3). These injuries are considered unstable due to their location and the relative lack of muscle and ligamentous support.

In pure flexion injuries below C2, a longitudinal pull is exerted on the strong nuchal ligament complex, which usually remains intact. Most of the force is expended on the vertebral body anteriorly, causing a simple wedge fracture. Radiographically, there is a diminished height and increased concavity of the anterior border of the vertebral body, an increased density of the vertebral body resulting from bony impaction, and prevertebral soft tissue swelling (Fig. 40-4). Because the posterior column remains intact, this injury is usually stable and rarely accompanied by nervous system damage. However, spinal instability may occur with severe wedge fractures (loss of more

than half the vertebral height) or multiple adjacent wedge fractures, and such injuries are best treated as being potentially unstable.

A flexion teardrop fracture results when severe flexion forces cause anterior displacement of a wedge-shaped fragment (resembling a teardrop) of the anteroinferior portion of the involved vertebral body (Fig. 40-5). Since this injury commonly involves ligamentous disruption, it is often associated with neurologic injury.

The clay shoveler’s fracture is an oblique fracture of the base of the spinous process of one of the lower cervical segments (Fig. 40-6). The injury derives its name from its common occurrence in clay miners in Australia during the 1930s. When a miner lifted a heavy shovelful of clay, abrupt head flexion against the supraspinous ligament resulted in an avulsion fracture of the spinous process. Today, this fracture is more commonly seen following direct trauma to the spinous process and after sudden deceleration MVCs that result in forced neck flexion. Since this injury involves only the spinous process, it is stable and not associated with neurologic involvement.

Pure spinal subluxation occurs when the ligamentous complexes rupture without an associated bony injury. This injury begins posteriorly in the nuchal ligament and proceeds anteriorly to involve other ligaments. The lateral radiograph with the neck in the neutral position may show a widening of both interspinous and intervertebral spaces posteriorly at the level of injury, and oblique views may demonstrate a widening or abnormal alignment of the facets (Fig. 40-7). These findings are often subtle and may be missed if flexion and extension views are not obtained. Although rarely associated with neurologic damage, this injury is potentially unstable.

Bilateral facet dislocations occur when a greater force of flexion causes soft tissue disruption to continue anteriorly to the annulus fibrosis of the intervertebral disk and the anterior longitudinal ligament, resulting in an extremely unstable condition. The forward movement of the spine causes the inferior articulating facets of the upper vertebra to pass upward and over the superior facets of the lower vertebra, resulting in anterior displacement of the spine above the level of injury.
Radiographically, the anterior displacement will appear to be greater than one half of the anteroposterior (AP) diameter of the lower vertebral body with the superior facets anterior to the inferior facets (Fig. 40-8).

**Shear Injury.** Trauma to the head directed in an AP direction may result in fracture of the odontoid process above the transverse ligaments (type I) or, more commonly, at the base of the odontoid process where it attaches to C2 (type II) (Fig. 40-9). Slight angulation of the force may result in extension of the fracture into the body of C2 (type III). Type II odontoid fractures are unstable and often complicated by nonunion. Spinal cord injury is uncommon but can occur.

**Flexion-Rotation.** Rotary atlantoaxial dislocation is an unstable injury visualized best on open-mouth odontoid radiographs (Fig. 40-10). If the skull is shown obliquely, there may be a false-positive asymmetry between the odontoid process and the lateral masses of C1. However, when the x-ray reveals symmetrical basilar skull structures, a unilaterally magnified lateral mass confirms a C1-C2 dislocation.

A unilateral facet dislocation involves both flexion and rotation. The rotational component of this injury occurs around one of the facet joints, which acts as a fulcrum. Simultaneous flexion and rotation cause the contralateral facet joint to dislocate, with the superior facet riding forward and over the tip of the inferior facet and coming to rest within the intervertebral foramen. In this position, the dislocated articular mass is mechanically locked in place, making this a stable injury, although the posterior ligament complex is disrupted. The frontal radiograph shows the spinous processes above the level of dislocation displaced from the midline in the direction of the rotation (Fig. 40-11A and B). The lateral radiograph shows a forward displacement of the dislocated segment on the vertebra below (less than half the AP diameter of this vertebral body) and a rotation of the dislocated vertebra and those above it (see Fig. 40-11C and D). Cervical fractures and dislocations may cause torticollis, but torticollis may also be due to a benign process such as a muscle spasm. It may be difficult to differentiate torticollis due to cervical fracture or dislocation from torticollis caused by severe muscle spasm, however, and oblique projections may be necessary to demonstrate the dislocated facet joint (see Fig. 40-11E and F).

Due to the varying shapes of the articular processes, particularly between the cervical and lumbar regions, different types of flexion-rotation injuries result. In the cervical region, where articular processes are small, flat, and almost horizontal, unilateral facet dislocations occur as described previously. In the lumbar region, however, where articular processes are large, curved, and nearly vertical, unilateral facet dislocation is rare. Instead, one or both articular processes fracture, and the upper vertebra swings forward. Commonly seen in the thoracolumbar and lumbar region, this rotation fracture-dislocation is unstable (Fig. 40-12).

**Extension.** The posterior neural arch fracture of the atlas (C1) results from the compression of the posterior elements between the occiput and the spinous process of the axis (C2) during forced neck extension (Fig. 40-13). Although the anterior arch and the transverse ligament remain intact, this fracture is potentially unstable because of its location.

The hangman’s fracture, or traumatic spondylolysis of C2, occurs when the cervicoocranium (the skull, atlas, and axis functioning as a unit) is thrown into extreme hyperextension as a result of abrupt deceleration. Bilateral fractures of the pedicles of the axis occur with or without dislocation (Fig. 40-14). Although this lesion is unstable, cord damage is often minimal because the AP diameter of the neural canal is greatest at the C2 level, and the bilateral pedicular fractures permit the spinal canal to decompress itself. Originally described in victims of hanging injury, today it is most often the result of head-on MVCs.

The extension teardrop fracture occurs when abrupt extension of the neck causes the anterior longitudinal ligament to pull...

the anteroinferior corner of a vertebral body away from the remainder of the vertebra, producing a triangular-shaped fracture that is radiographically similar to the flexion teardrop fracture (Fig. 40-15). Often occurring in lower cervical vertebrae (C5-C7) from diving accidents, this unstable injury may be associated with a central cord syndrome caused by the ligamentum flavum buckling into the spinal cord.6

**Vertical Compression.** Vertical compression injuries occur in the cervical and lumbar regions, which are capable of straightening at the time of impact. When forces are applied from either above (skull) or below (pelvis or feet), one or more vertebral body endplates may fracture. The nucleus pulposus of the intervertebral disk is forced into the vertebral body, which is shattered outward, resulting in a *burst fracture*. The lateral radiograph shows a comminuted vertebral body. The frontal radiograph demonstrates a characteristic vertical fracture of the vertebral body, which helps differentiate it from the simple wedge fracture and the flexion teardrop fracture. This is a stable fracture since all the ligaments remain intact. However, fracture fragments may impinge on or penetrate the ventral surface of the spinal cord and cause an anterior cord syndrome (see Fig. 40-15).

**Figure 40-15.** Burst fracture of a vertebral body. Mechanism: vertical compression/flexion. Stability: unstable. A and B. There is a compression fracture of the C4 vertebra. During the bursting process, the anterior segment of the fracture protrudes anteriorly and its posterior aspect protrudes posteriorly into the spinal canal. Such protrusion is often associated with anterior cord syndrome. The cervical spine is abnormally angulated. C and D, Lateral radiograph showing a burst fracture of L1, appearing very similar to a compression fracture. Mechanism: flexion. Stability: usually stable.
The Jefferson fracture of C1 is an extremely unstable injury that occurs when a vertical compression force is transmitted through the occipital condyles to the superior articular surfaces of the lateral masses of the atlas. This force drives the lateral masses outward, resulting in fractures of the anterior and posterior arches of the atlas and a disruption of the transverse ligament. Since this injury is often associated with prevertebral hemorrhage and retropharyngeal swelling, the lateral film may demonstrate a widening of the predental space between the anterior arch of C1 and the odontoid, or dens. The open-mouth view will demonstrate a bilateral offset of both right and left lateral masses of C1 relative to the lateral masses of C2. A fracture should be diagnosed when the sum of the offset distances from the right and left sides exceeds 7 mm (Fig. 40-16). However, when the fragments are minimally displaced, the Jefferson fracture is difficult to recognize, and computed tomography (CT) may be necessary.

Vertical compression fractures may rarely result in isolated fractures of the articular pillar or the vertebral body, exhibiting vertical and oblique lines of fracture.

Classification of Spinal Cord Injuries

Primary Spinal Cord Injury. The spinal cord may be injured in a number of ways. First, penetrating trauma or massive blunt trauma with disruption of the vertebral column may cause the...
Figure 40-16. Jefferson fracture. Mechanism: vertical compression. Stability: unstable. A and B, Bilateral lateral displacement of the lateral masses of C1 with respect to the articular pillars of C2 confirms a Jefferson fracture and differentiates it from fracture of the posterior neural arch of C1 on an anteroposterior view. C and D, Computed tomographic scan of C1 showing two fracture sites in the ring of C1 with lateral displacement of the lateral mass on the right.

The transection of neural elements. Since neurons within the central nervous system do not regenerate, such injuries are irreversible. Less severe blunt trauma may have similar effects resulting from a displaced bony fragment or a herniated disk. Second, when elderly patients with cervical osteoarthritis and spondylosis are subjected to forcible cervical spine extension, the spinal cord may be compressed between an arthritically enlarged anterior vertebral ridge and a posteriorly located hypertrophic ligamentum flavum (Fig. 40-17). This injury frequently results in a central cord syndrome.

Primary vascular damage to the spinal cord, a third mechanism of injury, may occur in several ways. The spinal cord may
be compressed by an extradural hematoma, particularly in patients who are on anticoagulants or have bleeding disorders. Vascular injuries should also be suspected when there is a discrepancy between the clinically apparent neurologic deficit and the known level of spinal injury. For example, a lower cervical dislocation may compress the vertebral arteries as they travel within the spinal foramina of the vertebrae. This compression may result in thrombosis and decreased blood flow through the anterior spinal artery that originates from both vertebral arteries at the level of C1 (Fig. 40-18). On physical examination, such an injury may erroneously appear to be localized to the level of C1 or C2. Also, the great radicular artery of Adamkiewicz, originating from the aorta and entering the spinal canal at the level of L1, sends branches as cephalad as T4. Therefore, a lumbar fracture or dislocation can produce a neurologic deficit as high as T4.

Secondary Spinal Cord Injury. The maximum neurologic deficit following blunt spinal cord trauma is often not seen immediately and may instead progress over many hours. The histopathology of the so-called secondary spinal cord injury has been studied extensively in experimental animal models. It is now thought that primary SCI initiates a complex cascade of events, involving free radical-induced lipid peroxidation reactions, which results in progressive ischemia of gray and white matter during the postinjury period (Fig. 40-19). Other factors, such as hypoxia, hypotension, hyperthermia, hypoglycemia, and mishandling by medical personnel, also affect the ultimate extent of SCI.

**CLINICAL FEATURES**

**Neurologic Evaluation**

The initial neurologic evaluation of a patient with a suspected spinal injury should begin with simple observation. Careful inspection of the patient’s entire body, beginning with the head and proceeding downward, may reveal telltale signs of possible spinal involvement. Significant head and facial trauma have a 5 to 10% incidence of associated cervical spine injuries. Scapular contusions suggest a rotation or flexion-
rotation injury of the thoracic spine. Chest and neck abrasions from automobile shoulder belts and lower abdominal markings from lap belts indicate possible blunt carotid and vertebral injuries, as well as spinal, intrathoracic, and intra-abdominal injuries. As occurs with falls from considerable heights, injuries to the gluteal region, calcaneal fractures, and severe ankle fractures suggest a compression type of spinal injury.

The patient should be observed for the presence and symmetry of both voluntary and involuntary movements. An abnormal breathing pattern may provide an important clue to a cervical injury. The diaphragm is innervated by the phrenic nerve, which originates at the C3-C4 level. The intercostal muscles of the rib cage are supplied by nerves that originate in the thoracic spine; thus, an abdominal breathing pattern indicates an injury below the C4 level. The presence of Horner's syndrome, characterized by unilateral ptosis, miosis, and anhidrosis, may result from a disruption of the cervical sympathetic chain, usually at the level of C7-T2. Priapism may occur with severe SCI.

The physician should speak with the patient during the inspection process. This important part of the patient’s assessment should not be overlooked in trauma cases because it provides the patient with reassurance and the physician with valuable information. Patients may experience pain in the sensory dermatome corresponding to the level of the spinal injury. For example, a C2 lesion may cause occipital pain, whereas discomfort in the area of the trapezius muscle, particularly in the absence of signs of local trauma, suggests a C5 injury. The past medical history is important because certain conditions predispose patients to cervical injury. For example, patients with Down syndrome are predisposed to atlanto-occipital dislocation, whereas those with rheumatoid arthritis are prone to rupture of the transverse ligament of C2 with even minor trauma.

Palpation of the entire spine and paraspinal musculature may reveal areas of tenderness, deformity, or muscle spasm. A “gibbus” deformity or step-off may be appreciated with severe subluxation. Widening of an interspinous space indicates a tear in the posterior ligament complex and a potentially unstable spinal injury.

The motor activity of the body is complex. Since a single motion is often governed by muscles innervated by multiple spinal segments, localizing a spinal lesion based solely on an assessment of motor function is extremely difficult. Testing the presence and strength of those motions outlined in Table 40-2, however, provides a rapid baseline assessment. When a deficit is noted, the motor examination and the remainder of the neurologic examination should be repeated at frequent intervals because progression of dysfunction may occur. If there is apparent total loss of function, every effort should be made to elicit the most minimal of motor responses since any response markedly alters the prognosis for recovery. A slight toe flicker in an otherwise paralyzed individual indicates that the patient may again eventually walk unassisted.

*Sensory examination is best accomplished with the sensory dermatome chart (Fig. 40-20). After locating an area of hypesthesia, one should carefully delineate the area by slowly moving the stimulus from areas of decreased sensation outward, rather than the reverse, because patients are much more sensitive to the appearance of sensation than to its disappearance. This test should be performed first with a cotton wisp to assess sensitivity to light touch, a posterior column function. A pin should then be used to assess pain sensation, which is an anterior spinothalamic tract function. The presence of islands of sparing of sensation within an affected dermatome or below the level of apparent total dysfunction, even in the presence of complete motor paralysis, indicates that the patient has a very good chance of functional motor recovery. An accurate baseline sensory examination is imperative because a cephalad progression of hypesthesia is the most sensitive indicator of deterioration. When this is observed in the cervical region, one should anticipate impending respiratory failure and take steps to ensure airway stabilization.

The presence of cord-mediated deep tendon reflexes can be helpful as a localizing, diagnostic aid (Table 40-3). Classically, muscle paralysis associated with intact deep tendon reflexes indicates an upper motor neuron (spinal cord) lesion, whereas paralysis associated with absent deep tendon reflexes indicates a lower motor neuron (nerve root or cauda equina) lesion. This differentiation is important because the latter condition is often caused by a surgically correctable lesion. After the initial period of areflexia, reflexes gradually return after 1 to 3 days, and after 1 to 4 weeks, patients with SCI will manifest characteristic hyperreflexia and spasticity. However, since reflexes are typically absent during the initial phase of spinal shock, the examination of reflexes is less useful in the emergency department.

Complete Spinal Cord Lesions

A complete spinal cord lesion is defined as total loss of motor power and sensation distal to the site of an SCI. Functional motor recovery is rare in patients with a total cord syndrome that persists for longer than 24 hours after the injury. Before diagnosing a total cord syndrome, however, two points should be considered. First, any evidence of minimal cord function, such as sacral sparing, excludes the patient from this group. Signs of sacral sparing include perianal sensation, normal rectal sphincter tone, or flexor toe movement. The presence of any of these signs indicates a partial lesion, usually a central cord syndrome, and the patient may have marked functional recovery, including bowel and bladder control and eventual ambulation.

Second, it is important to note that a complete spinal cord lesion may be mimicked by a condition known as spinal shock. Spinal shock results from a concussive injury to the spinal cord that causes total neurologic dysfunction distal to the site of injury. Spinal shock may persist for a few days or a few weeks. The end of spinal shock is heralded by the return of the bulbocavernous reflex, which is a normal cord-mediated reflex elicited by placing a gloved finger in the patient’s rectum and then squeezing the glans penis or clitoris or by tugging gently on the Foley catheter. An intact reflex results in rectal sphincter contraction. Absence of this reflex indicates the presence of spinal shock, during which time the patient’s prognosis cannot be accurately assessed. A complete spinal cord lesion will remain unchanged following the cessation of spinal shock.

Incomplete Spinal Cord Lesions

Approximately 90% of incomplete spinal injuries can be classified as one of three clinical syndromes: the central cord syndrome, the Brown-Séquard syndrome, and the anterior cord syndrome (Fig. 40-21). The most common is the central cord syndrome, which is often seen in patients with degenerative arthritis of the cervical vertebrae when their necks are hyperextended. The ligamentum flavum buckles into the cord, resulting in a concussion or contusion of the central portion of the cord, which affects the central gray matter in the most central portions of the pyramidal and spinothalamic tracts. Since fibers that innervate distal structures are located in the
periphery of the spinal cord, these patients have a greater neurologic deficit in the upper extremities than in the lower extremities. With more severe injuries, patients may appear to be almost completely quadriplegic and have only minimal evidence of sacral sparing. The prognosis for patients with this syndrome is variable. More than 50% of patients with a severe central cord syndrome become ambulatory and regain bowel and bladder control, as well as some hand function.

The Brown-Séquard syndrome, or hemisection of the spinal cord, usually results from penetrating trauma but may also be seen following lateral mass fractures of the cervical spine. Patients with this lesion have ipsilateral motor paralysis and contralateral sensory hypesthesia distal to the level of injury; however, either finding may predominate depending on the exact location and extent of injury. Moreover, since the fibers of the lateral spinal thalamic tract cross at a different level to the contralateral side, the pain and temperature loss may be found variably one or two segments above the lesion. Virtually all patients maintain bowel and bladder function and unilateral motor strength, and most become ambulatory.

The anterior cord syndrome usually results from hyperflexion injuries causing cord contusion, by the protrusion of a bony fragment or herniated disk into the spinal canal, or by laceration or thrombosis of the anterior spinal artery. This syndrome is characterized by paralysis and hypalgesia below the level of injury with preservation of posterior column functions, including position, touch, and vibratory sensations. Suspicion for an acute anterior cord syndrome warrants immediate neurosurg-
dysphonia, hiccups, nausea, vomiting, dizziness or vertigo, and cerebellar ataxia. The Dejerine onion skin pattern of analgesia of the face is caused by damage to the spinal trigeminal tract. Horner’s syndrome results from damage to the cervical sympathetic chain and is characterized by ipsilateral ptosis, miosis, and anhidrosis. Injuries below the L2 level can result in an acute cauda equina syndrome, characterized by perineal or bilateral leg pain, bowel or bladder dysfunction, perianal anesthesia, diminished rectal sphincter tone, and lower extremity weakness.

The syndrome of spinal cord injury without radiographic abnormality (SCIWORA) is seen primarily in younger children but may occur in any age group. The mechanism is unclear but has been ascribed to the increased ligamentous elasticity seen in the young, leading to transient spinal column subluxation, stretching of the spinal cord, and vascular compromise. Patients often experience a brief episode of upper extremity weakness or paresthesias followed by neurologic deficits that appear hours to days later. The prognosis for patients with SCIWORA is variable, depending on the degree of neurologic impairment and the rate of resolution.

**Diagram 40-22.** Mechanism of vertebral artery injury in extension injuries of the cervical spine.

diagnostic consultation since it may be due to a surgically correctable lesion. Following surgical intervention, patients have variable degrees of recovery during the first 24 hours but little improvement thereafter.

There are several less common spinal cord syndromes that may result from a direct injury to the cervicomedullary junction and upper cervical segments or from vertebral artery occlusion due to severe hyperextension (Fig. 40-22). The posteroinferior cerebellar artery syndrome may produce dysphagia, hiccup, nausea, vomiting, dizziness or vertigo, and cerebellar ataxia. The Dejerine onion skin pattern of analgesia of the face is caused by damage to the spinal trigeminal tract. Horner’s syndrome results from damage to the cervical sympathetic chain and is characterized by ipsilateral ptosis, miosis, and anhidrosis. Injuries below the L2 level can result in an acute cauda equina syndrome, characterized by perineal or bilateral leg pain, bowel or bladder dysfunction, perianal anesthesia, diminished rectal sphincter tone, and lower extremity weakness.

The syndrome of spinal cord injury without radiographic abnormality (SCIWORA) is seen primarily in younger children but may occur in any age group. The mechanism is unclear but has been ascribed to the increased ligamentous elasticity seen in the young, leading to transient spinal column subluxation, stretching of the spinal cord, and vascular compromise. Patients often experience a brief episode of upper extremity weakness or paresthesias followed by neurologic deficits that appear hours to days later. The prognosis for patients with SCIWORA is variable, depending on the degree of neurologic impairment and the rate of resolution.

**DIAGNOSTIC STRATEGIES**

**Radiographic Evaluation**

**Indications**

Clinicians have historically taken a liberal approach to ordering cervical spine radiographs in the setting of trauma since failure
to recognize an SCI may result in devastating neurologic consequences. According to the National Hospital Ambulatory Care Survey, only 4% of all cervical spine radiographs demonstrate a fracture. There is also great practice variation among emergency physicians, with a sixfold range in radiography ordering rates.

In an effort to standardize clinical practice and guide physicians to be more selective in their use of radiography without jeopardizing patient care, two clinical decision rules have been developed. The first rule to be developed, the National Emergency X-Radiography Utilization Study (NEXUS) Low-Risk Criteria (NLC), was based on a multicenter prospective observational study involving 34,069 trauma patients seen at 21 U.S. emergency departments. The decision instrument required patients to meet five criteria in order to be classified as having a low probability of injury: (1) no midline cervical tenderness; (2) no focal neurologic deficit; (3) normal alertness; (4) no intoxication; and (5) no painful, distracting injury. The decision rule identified all but 8 of the 818 patients who had spinal injuries. Only 2 of these patients had a clinically significant injury, whereas only 1 required surgical stabilization, and neither sustained a permanent neurologic injury. Sensitivity, specificity, and negative predictive value of the NLC were calculated and were respectively found to be 99.6, 12.9, and 99.8%.  

Due to concerns about the low specificity of the NLC, Stiell and colleagues developed the Canadian C-spine rule (CCR) based on 25 selected clinical predictor variables associated with spine injury. In 2003, the CCR was prospectively studied and compared to the NLC in the nine Canadian tertiary care hospitals. Of 8283 patients, 162 were found to have “clinically significant” injuries, and the sensitivity, specificity, and negative predictive value of the CCR were respectively 99.4, 45.1, and 100%. The CCR is composed of the following three questions:

1. Are there any high-risk factors that mandate radiography?
2. Are there any low-risk factors that allow safe assessment of range of motion?
3. Is the patient able to actively rotate his or her neck 45 degrees to the left and right?

High-risk factors include age older than 65 years, a “dangerous mechanism of injury” (a fall from a height >1 m, an axial loading injury, high-speed motor vehicle crash [>100 km/hr], rollover, ejection, motorized recreational vehicle, or bicycle collision), or the presence of paresthesias. Low-risk factors include simple rear-end vehicle crashes, sitting position in the emergency department, ambulatory at any time, delayed onset of neck pain, and the absence of midline neck tenderness. Although the NEXUS criteria are more widely utilized in the United States, both studies support the recommendation that cervical spine radiographs be obtained only for patients in whom spinal injury is suspected based on clinical assessment.

There is some controversy as to which of the two rules to implement. There are methodologic differences in the respective study designs, such as different inclusion and exclusion criteria. Prior to the widespread application of any prediction rule, external validation is necessary to assess its generalizability. Nevertheless, the use of either rule has been shown to significantly limit the number of unnecessary radiographs while missing only rare patients with clinically significant injuries.

**Cervical Plain Radiographs**

Normal cervical spine radiographs in AP, lateral, swimmer’s, oblique, and odontoid views are presented in Figures 40-23 and 40-24. All vertebrae suspected of being injured must be visualized. The C7-T1 vertebra may be obscured in muscular or obese patients, as well as in patients with spinal lesions that result in paralysis of the muscles that act to depress the shoulders. The paralysed leaves the trapezius muscles, which elevate the shoulders, unopposed. Such lesions are located in the lower cervical region. The shoulders can usually be depressed by pulling the patient’s hands toward the feet, using slow, steady traction. Movement should occur only at the shoulder girdle while the head and neck remain immobilized. Note that the head and neck should not be pulled in opposition to the person pulling down the shoulders because this may induce a distraction injury. If this maneuver is unsuccessful or difficult to perform because of upper extremity injuries, a transaxillary or swimmer’s view of the lower cervical vertebrae may be helpful. The upper three or four thoracic vertebrae are also difficult to visualize on routine lateral views of either the cervical or thoracic spine, and a swimmer’s view, an oblique radiograph, or CT is often needed for adequate evaluation of the thoracic spine.

Although the cross-table lateral view of the cervical spine is the most helpful x-ray in diagnosing spinal injuries, its inadequacy as the sole view is well documented. Since the diagnostic yield is significantly increased when the AP and odontoid views are included, all three views of the cervical spine should be evaluated prior to discontinuation of cervical spine immobilization. The NLC shows that a technically adequate three-view trauma series will fail to diagnose spinal injury in only .07% of patients with injuries and in only .008% of patients with unstable injuries.

**Cross-Table Lateral View.** The inspection of the lateral cervical spine film should be methodical and complete. To do this, it is helpful to remember the “ABCs” of interpreting the lateral film, where A stands for alignment, B for bony abnormalities, and C for cartilage-space assessment, and S for soft tissues.

To check the alignment, two imaginary lines are drawn that separately connect the anterior and posterior margins of the vertebral bodies, the anterior and posterior contour lines. A third line, the spinolaminar line, connects the bases of the spinous processes extending to the posterior aspect of the foramen magnum (Fig. 40-25). All three lines should form a smooth, continuous lordotic curve, and any disruption of these lines suggests a bony or ligamentous injury. An exception to this rule is the pseudosubluxation of C2 and C3, which is commonly seen in infants and children. This phenomenon is attributed to their immature muscular development and a hypermobile spine. Thus, if a high cervical injury is suspected in a child, the posterior cervical line, which connects the points bisecting the bases of the spinous processes of C1 and C3, should be used (Fig. 40-26). If the base of C2 lies more than 2 mm anterior or posterior to the posterior cervical line, an injury at that level should be suspected. On the lateral view, the predental space is the distance between the anterior aspect of the odontoid process and the posterior aspect of the anterior ring of C1, should not exceed 3 mm in an adult or 5 mm in a child (see Fig. 40-26). A widening of this space may indicate a Jefferson fracture of C1.

Next, bony abnormalities should be assessed. Subtle changes in bony density should be noted. Areas of decreased density, seen in patients with rheumatoid arthritis, osteoporosis, or metastatic osteolytic lesions, are more apt to succumb under stress. Acute compression fractures of the vertebral bodies and metastatic osteoblastic lesions result in areas of increased bone density.

The emergency physician may diagnose subluxations and dislocations through cartilage-space assessment. A slight anterior or posterior widening of the intervertebral space or

dren younger than age 15 years. In children younger than age
sign of an underlying bony or soft tissue injury.

anterior bulging of the prevertebral fat stripe is an excellent
of the esophagus or some portion of the respiratory tree, and
trachea, should not exceed 22
anterior border of the body of C6 to the posterior wall of the
muscle. Here, the retrotracheal space, measured from the
space is widened by the esophagus and the cricopharyngeal
at that level. Below the level of C4, the prevertebral soft tissue
or should be less than one half the width of the vertebral body
level of C3 and C4, this measurement should not exceed 5
mm in children or adults (see Fig. 40-27A and B). The normal interlami-
overlapping laminae have the appearance of shingles on a roof
(see Fig. 40-23E and F). Normal laminar ellipses on an oblique view, should be equidistant. An increased interlaminar distance, due to lack of capsular liga-

the interspinous space may be the only clue to an unstable
dislocation.

Finally, the soft tissues of the retropharyngeal space should be assessed for the presence of prevertebral swelling and hem-
orrhage, often the only radiographic sign of spinal injury. The retropharyngeal space, measured from the anterior border of the body of C2 to the posterior wall of the pharynx, should not exceed 7 mm in children or adults (Fig. 40-27A and C). At the level of C3 and C4, this measurement should not exceed 5 mm or should be less than one half the width of the vertebral body at that level. Below the level of C4, the prevertebral soft tissue space is widened by the esophagus and the cricopharyngeal muscle. Here, the retrotracheal space, measured from the anterior border of the body of C6 to the posterior wall of the trachea, should not exceed 22 mm in adults or 14 mm in children younger than age 15 years. In children younger than age 2 years, the retropharyngeal space may normally appear widened during expiration; thus, inspiratory films should be obtained. Air in the prevertebral space may indicate rupture of the esophagus or some portion of the respiratory tree, and anterior bulging of the prevertebral fat stripe is an excellent sign of an underlying bony or soft tissue injury.

**Odontoid View.** The second film obtained in the emergency department is the open-mouth or closed-mouth view of the atlas and axis (see Fig. 40-24G-J). Nonfusion of the odontoid in children and congenital anomalies of the odontoid in adults may mimic fractures.

**AP View.** The AP spinal film completes the spinal series. The spinous processes should form a straight line, and the laryngeal and tracheal air shadows should be midline (see Figs. 40-23B and 40-27D). The regular outline of the lateral masses should be verified, and the pedicles viewed end on can be checked for fracture. Widening of the interpedicular distance compared to adjacent vertebrae suggests a burst fracture (Fig. 40-28).

In addition to searching for fractures of vertebral bodies and transverse processes, bulging of the mediastinal stripe may be the only evidence of a thoracic vertebral body fracture. Fractures of the upper thoracic vertebrae may cause a posterior mediastinal hemorrhage that produces mediastinal widening on the chest x-ray similar to that seen with aortic rupture.

**Oblique Views**

Oblique views of the cervical spine may be helpful to confirm a suspected posterior laminar fracture, a unilateral facet disloca-
tion, or a real subluxation. However, with the advent of high-
resolution computed tomography, suspicion of these injuries on plain films ordinarily leads to CT rather than the obtaining of oblique views. The normal lamina appears as an intact ellipse (see Fig. 40-23E and F), and a posterior laminar fracture disrupts the appearance of this ellipse (Fig. 40-29). Normal overlapping laminae have the appearance of shingles on a roof (see Fig. 40-27A and B). Integrity of these shingles excludes the presence of a unilateral facet dislocation, whereas disruption confirms it (see Fig. 40-11E and F). The normal interlami-
nar distance, measured from the center points of successive laminar ellipses on an oblique view, should be equidistant. An increased interlaminar distance, due to lack of capsular liga-

**Flexion and Extension Views**

Flexion and extension (F/E) views are often obtained when there is concern for ligamentous injury, despite negative stan-
dard radiographs. Instability of the cervical spine is suggested by any of the following: more than 3.5 mm of horizontal dis-
placement between the disks, displaced apophyseal joints, widened disk spaces, loss of greater than 30% of the disk height, or the presence of a prevertebral hematoma. The exact role and timing of the use of F/E views are controversial, however. The NEXUS investigators demonstrated that 86 of the 818 (10.5%) patients ultimately found to have cervical injury underwent F/E testing. Although 2 patients had bony injuries and 4 patients had subluxations demonstrated only on F/E views, all 6 patients had other injuries apparent on routine radiographs. In the acute setting, F/E radiographs have been reported to have unacceptably high false-positive and false-
negative rates since minor subluxations may be masked by concomitant muscle spasm. Thus, delayed F/E views obtained a week or two following injury may be more helpful. Moreover, other studies, such as CT and magnetic resonance imaging (MRI), appear to be superior imaging modalities in patients with severe, localized symptoms who have normal radiographs.

**CT Scan**

Conventional radiography is limited as a result of the nature of equipment, difficulties in positioning, lack of patient coop-
Figure 40-27. A and B, Normal structural relationships of the cervical spine laminae in an oblique view form a “shingles on a roof” appearance. C and D, Normal relationship between soft tissues and bony structures of the cervical spine in the lateral and anteroposterior (AP) views. C, In the lateral view, the intervertebral spaces and interspinous spaces should be compared with the spaces above and below for asymmetry and important clues in flexion and extension injuries. The retropharyngeal and retrotracheal soft tissues are measured at the C2 and C6 levels for swelling. D, In the AP view, the tracheal and laryngeal air shadows should be within the midline. A straight line should connect points bisecting the spinous processes. If such is not the case, rotatory injuries must be suspected.
A study comparing CT to plain radiography demonstrated the sensitivity in the detection of spine fractures to be 70% for plain radiography compared with 100% for CT, and there was a significant reduction in mean time in the radiology department with CT (1.0 vs. 1.9 hours, \( P < .001 \)). In another study, CT identified 99.3% of all fractures of the cervical, thoracic, and lumbar spine after high-energy trauma, and those missed by CT required minimal or no treatment.39,40

Due to the advantages of CT, some authorities argue that routine plain radiographs of the spine are unnecessary when CT is readily available. Investigators have assessed whether data collected from CT scans of the abdomen and pelvis obtained for the evaluation of chest and abdominal injuries provide sufficient data to screen for spinal fractures, thereby decreasing the time and cost of spine injury evaluation. In a retrospective review of 3537 blunt trauma patients, of whom 236 (7%) sustained a cervical, thoracic, or lumbar fracture, Brown and colleagues reported that CT identified 99.3% of all fractures. The one cervical and one thoracic fracture missed by CT respectively required minimal treatment with a rigid cervical collar or no treatment.39 CT is also thought to be adequate to clear cervical spines even in the obtunded blunt trauma patient.41 In fact, the Eastern Association for the Surgery of Trauma practice management guidelines recommend clearance of the cervical spine after performance of a CT of C1-C2 and three views of the cervical spine in the unreliable, obtunded patient.42 However, there remains controversy regarding clearance of the cervical spine in the obtunded patient.

The spiral (helical) CT scan provides continuous acquisition of data (volume scan) via a rotating x-ray tube and simultaneous patient movement through the CT gantry (Fig. 40-34). The ability to reconstruct axial CT data in two-dimensional and three-dimensional formats is helpful to nonradiologists, who are less accustomed to performing the mental integration
Figure 40-30. A and B, True subluxation, lateral view. Anterior subluxation of C5 on C6 is questionable. C and D, True subluxation, oblique view. The pedicle of C5 lies slightly anterior to that of C6, thus confirming subluxation.

Figure 40-34. Technique for performing a spiral computed tomographic scan.

Potential disadvantages of CT include cost and radiation exposure. However, in one study, although CT was associated with higher mean overall spinal imaging charges than plain radiography ($4386 vs. $513, P < .001), there was no statistically significant difference when comparing spinal imaging cost per patient ($172 vs. $164, p > .05). In the same study, radiation exposure for CT was higher than for plain radiography for cervical spine imaging (26 vs. 4 mSv), but CT had lower levels of radiation exposure for thoracolumbar imaging (13 vs. 26 mSv).

MRI Scan

MRI, with its superior resolution and lack of ionizing radiation, also has the primary advantage of the ability to directly image
nonosseous structures, including intramedullary and extra-
medullary spinal abnormalities that potentially cause neuro-
logic deficit (Fig. 40-37). Its major impact has therefore been
in demonstrating potentially surgical correctable lesions,
including acute disk herniation, ligamentous injury, bony com-
presion, epidural and subdural hemorrhage, and vertebral
artery occlusion (Fig. 40-38). MRI can identify three separate
patterns of SCI, including acute cord hemorrhage, cord edema
or contusion, and mixed cord injury. Patients with cord edema
or contusion show significant neurologic improvement, whereas
those with cord hemorrhage (Fig. 40-39) fare far worse. MRI
therefore has diagnostic and prognostic capabilities in the
evaluation of cervical spine injury. MRI is also viewed as the
best diagnostic imaging modality for SCIWORA, in which
MRI may demonstrate central disc herniation, spinal stenosis,
cord edema, and contusion.

Contraindications to MRI include the presence of a pace-
maker, cerebral aneurysm clips (MRI-compatible clips are
now available), and metallic (ferromagnetic) foreign bodies.
In addition, MRI cannot be used when MRI-incompatible
life-support, monitoring systems, and cervical traction devices
are employed (although MRI-compatible support systems
exist). Plain films and CT are still superior to MRI in evaluat-
ing osseous anatomy and fractures, particularly posterior-
element fractures.

The role of MRI in the evaluation of acute cervical spine
trauma continues to evolve, and some advocate an immediate
MRI in patients with clinical signs or plain film evidence sug-
gesting ligamentous injury, particularly when prevertebral
swelling is noted (Fig. 40-40). Most recommend MRI for
patients with a strong clinical suggestion of an occult spine
injury who have normal plain radiographs, including those
with persistent neck pain or neurologic deficit. However, when
CT findings are normal, some studies have demonstrated that
MRI may not be necessary to exclude unstable injuries, even
in the obtunded or “unreliable” patient. MRI is useful in
the evaluation of the previously traumatized spinal cord.
Progressive neurologic dysfunction in a previously stable
cord-injury patient may indicate undiagnosed disk or bone
impingement on the spinal cord, myelomalacia, a developing

![Figure 40-35. Three-dimensional computed tomography images of the cervical vertebrae. A, Superior view. B, Oblique view.](image-url)
intramedullary (post-traumatic) syrinx, or subarachnoid cystic changes (Fig. 40-41), which can all be diagnosed by MRI.

**MANAGEMENT**

A spinal injury should be suspected in all trauma victims with an unknown or suggestive mechanism of injury associated with complaints of neck or back pain, evidence of significant head or facial trauma, spinal tenderness, signs of focal neurologic deficit, impaired consciousness, potentially distracting injuries, or unexplained hypotension. All patients suspected of having a significant spinal injury should be approached in a manner similar to that outlined in Figure 40-42.

**Spinal Column Stabilization**

**Out-of-Hospital Care**

Paramedical personnel should suspect a spinal injury in any victim of trauma, especially craniofacial injuries caused by motor vehicle accidents, assaults, falls, and sports. Trauma victims may have an altered state of consciousness resulting...

Figure 40-41. Magnetic resonance image showing post-traumatic syrinx of the spinal cord.
Emergency Department

Trauma victims who arrive at the emergency department with spinal immobilization should be quickly assessed by a physician. If the probability of spinal injury is moderate to high, it is advisable to remove the patient’s clothes, evaluate any associated injuries, and perform resuscitative maneuvers without removing the immobilization apparatus. When the probability of injury is low, the immobilization device may be removed and the patient carefully assessed before further tests are ordered.

Patients with probable spinal injury who are conscious and cooperative should be cautioned against attempted movement until radiographic studies have been performed. Patients who are uncooperative because of head injury, drug or alcohol intoxication, hypotension, or the presence of multiple painful injuries require a more aggressive approach, including consideration of the use of chemical sedation and mechanical restraints. Suspected thoracic and lumbar spinal injuries are best managed by simply keeping the patient supine and immobile. The goal of stabilization in cases of cervical spine trauma is the immobilization of both the neck and the body because any movement may extend the initial injury. If the patient is not already immobilized on a backboard, the torso should be firmly anchored to the examining table by straps or rolled sheets. Supportive blocks or sandbags can be placed on either side of the head and a piece of 3-inch tape then placed across the forehead and blocks to immobilize the head and neck. A combative patient may require an individual assigned to hold the patient’s head in alignment with the longitudinal axis of the body. Sedation, drug-induced paralysis, and intubation may be required for patients who pose a danger to themselves because of excessive movement. Spinal precautions should be maintained in patients with an altered sensorium until the presence of an injury can be excluded clinically or radiographically. Suctioning should be immediately available to prevent aspiration, and emergency department personnel must be aware of this ever-present possibility. When vomiting occurs, patients should immediately be placed on their side, while spinal alignment is maintained, and suctioning performed.

Airway Management

The emergency physician should anticipate airway management problems in patients with cervical spinal injuries. Lesions above the level of C3 may cause immediate respiratory paralysis, and lower lesions that are ascending from the spread of edema may cause delayed phrenic nerve paralysis, as well as ascension of the neurologic injury above the level of C3. Cervical injuries may also be associated with airway obstruction from retropharyngeal hemorrhage or edema or maxillofacial trauma. In addition to head or chest injuries requiring airway control or respiratory support, acute pulmonary edema has also occurred after cervical spine injuries unassociated with significant head injury.

According to the American College of Surgeons’ (ACS) advanced trauma life support guidelines, the preferred method of airway management for patients with traumatic cardiopulmonary arrest, even with evidence of spinal injury, is rapid sequence intubation (RSI) with orotracheal intubation in the presence of in-line spinal stabilization. This is also the recommended approach for patients who are breathing but unconscious and in need of airway control or ventilatory support. The value of in-line spinal stabilization has been questioned in a review of the topic that notes that the data supporting the use of in-line stabilization come from cadaver
Spinal Shock

*Spinal shock* is a clinical syndrome characterized by the temporary loss of neurologic function and autonomic tone below the level of an acute spinal cord lesion. Patients usually exhibit flaccid paralysis with loss of sensation, deep tendon reflexes, and urinary bladder continence, along with bradycardia, hypotension, hypothermia, and intestinal ileus. Spinal shock may last from 24 hours to more than 2 weeks. Its cessation is heralded by the return of the bulbocavernous reflex.

*Neurogenic hypotension* secondary to spinal shock, which is caused by loss of vasomotor tone and lack of reflex tachycardia from disruption of autonomic ganglia, should always be a diagnosis of exclusion in the trauma victim. It should not be considered the cause of hypotension unless the patient is flaccid and areflexic; reflex tachycardia and peripheral vasoconstriction are absent; and, most important, the possibilities of coexisting hemorrhagic shock, cardiac tamponade, or tension pneumothorax have been eliminated. The absence of vasomotor activity in patients experiencing neurogenic hypotension can mask the usual presentation of these life-threatening injuries.

Although there is no consensus in the literature regarding the most appropriate treatment of neurogenic hypotension, it is prudent to begin the resuscitation of all newly arrived, hypotensive trauma victims with crystalloid fluid infusion. Most cases of pure neurogenic hypotension are mild (e.g., systolic blood pressure >90) and will initially respond to this approach. Severe (e.g., systolic blood pressure <70) neurogenic hypotension, seen in 20 to 30% of all spinal injuries, occurs most commonly with severe high cervical injuries associated with total or near-total loss of neurologic function. Fluid resuscitation is often ineffective in such patients and may result in fluid overload if aggressively pursued. As a result, symptomatic neurogenic hypotension should be managed with fluids, Trendelenburg positioning (unless contraindicated because of concomitant head injury), vasopressors, or cardiac pacing—based on hemodynamic monitoring—once the diagnosis is established and the coexistence of other causes of traumatic shock is excluded.

**Pharmacologics for Incomplete Cord Injury**

Experimental animal models of SCI support the concept that delayed biochemical damage, occurring hours to days following an initial traumatic insult, contributes to ongoing tissue loss and worsening neurologic function. As a result, numerous neuroprotective treatment strategies have been investigated in both laboratory animal studies and human clinical trials, and the search for an effective treatment is under way (Box 40-1). Methylprednisolone is currently the only agent routinely used for human victims of SCI, and its use is highly controversial.

The National Acute Spinal Cord Injury Study (NASCIS) investigators published several studies showing that early administration of high-dose methylprednisolone improves the neurologic outcome of SCI victims. Methylprednisolone is administered as an initial 30 mg/kg IV bolus followed by an infusion of 5.4 mg/kg/hr. The infusion is maintained for 24 hours in patients who are treated within 3 hours of injury, and it is maintained for 48 hours in patients who are treated within 3 to 8 hours following injury. The administration of steroids resulted in a worse outcome when started after 8 hours.
methylprednisolone actually results in an improvement in day-to-day functioning. More, other studies have reported that patients treated with methylprednisolone have a higher rate of respiratory and gastrointestinal complications compared with placebo-treated patients. The most recent guidelines published by the Consortium for Spinal Cord Medicine (which includes the American Association of Neurological Surgeons, the American College of Emergency Physicians, the Congress of Neurological Surgeons, the American Association of Orthopaedic Surgeons, and the International Spinal Cord Society) in 2008 state that “no clinical evidence exists to definitively recommend the use of any neuroprotective pharmacologic agent, including steroids, in the treatment of acute spinal cord injury to improve functional recovery.” Despite this, the Cochrane Database Systematic Review maintains that “high-dose methylprednisolone steroid therapy is the only pharmacologic therapy shown to have efficacy in a Phase Three randomized trial when it can be administered within 8 hours of injury … and that there may be additional benefit by extending the maintenance dose from 24 to 48 hours if treatment is not started until between 3 and 8 hours after injury.” Although a recent survey of U.S. spine surgeons found that 86% routinely administer steroids to spine-injured patients, only 21% believed that it improved patient recovery and the most common justification given for administering steroids was “medicolegal concerns.” A similar survey of emergency departments and neurosurgical units in the United Kingdom found wide variations in practice. At this time, however, there is no substantive evidence to support the utilization of prednisolone for acute blunt partial SCI, and because of the possibility of severe side effects, its use can only be considered, at best, an option.

**Associated Injuries**

**Cardiopulmonary**

Deterioration in a trauma victim’s cardiopulmonary status is usually the result of hemorrhagic shock or direct injury to the heart or lungs, it may reflect the development of pulmonary edema that occasionally occurs in response to brain and spinal cord injury. Spinal cord trauma may stimulate an intense sympathetic discharge with two subsequent effects. First, pulmonary capillary endothelial cells are disrupted, leading to the pulmonary capillary leak syndrome, in which pulmonary edema occurs in the presence of normal pulmonary artery pressures (<18 mm Hg). Second, marked increases in afterload may cause left ventricular dysfunction, leading to pulmonary edema associated with a high pulmonary artery pressure (>18 mm Hg). Volume overload from aggressive fluid resuscitation can also contribute to the development of pulmonary edema. As a result, the management of such patients is often complex and may require the careful balancing of fluid requirements, afterload reducing agents, and artificial ventilation with positive end-expiratory pressure.

**Gastrointestinal and Genitourinary**

If SCI renders the abdominal examination unreliable, an abdominal CT scan, ultrasound, diagnostic peritoneal lavage, or some combination is often necessary. During the acute stages of SCI, both the gastrointestinal tract and the bladder become atonic. Thus, once a patient has been stabilized, a nasogastric tube should be placed to prevent gastric distention, and a Foley catheter should be placed to prevent bladder distention and to monitor fluid output. Gastrointestinal bleeding from stress ulcers occurs in 2 to 20% of spinal trauma patients. Thus, either ulcer prophylaxis with histamine H2 receptor antagonists or proton pump inhibitors should be initiated.

**Skin**

Denervated skin is extremely susceptible to pressure necrosis. Pressure sores can develop in less than 1 hour in such patients, particularly if they are managed on unpadded spinal carts. Padding pressure areas with sheepskin or foam padding early in the course of therapy can help minimize decubitus ulcers.

**Definitive Treatment and Prognosis**

The role of immediate surgical intervention in the management of spinal injuries is currently limited to relieving impingement on the spinal cord caused by foreign bodies, herniated disks, bony fracture fragments, or an epidural hematoma. Surgery may be necessary later to stabilize severe bony injuries or to reduce spinal dislocations. The timing of surgical intervention is controversial, and there are no well-designed studies that have determined whether early (<12 hours) versus late decompression is beneficial.

Major spinal injuries were once almost uniformly fatal. Most patients died of pulmonary complications or sepsis resulting from skin necrosis or urinary infection. The advent of antibiotic therapy made long-term survival not only possible but also expected. Today, patients with SCIs are best managed by early referral to regional spine centers, a team of neurosurgeons, orthopedic surgeons, psychologists, and physical therapists can initiate rehabilitation. Specialized SCI treatment centers offer patients a chance to return to a productive life within the limits of their disability. Experience has shown that with the exception of those patients with high cervical lesions (above C5), most patients attain sufficient independence to live outside of a high-level care environment.

**DISPOSITION**

**Cervical Sprain**

Musculoskeletal injuries of the spine involving only mild to moderate discomfort and no neurologic impairment, no abnormal radiographic findings, and no other injuries requiring hospitalization are best managed on an outpatient basis. Treatment should include analgesics and referral for follow-up evaluation. Up to 27% of patients experiencing neck pain in the emergency department following trauma will continue to have symptoms at 1 year.

**Minor Fractures**

Most patients with spinal fractures require hospitalization. Patients with isolated cervical vertebral body compression fractures or spinous process fractures may be managed on an outpatient basis if the mechanism of injury is not significant, there is no evidence of neurologic impairment or associated ligamentous instability, and the degree of patient distress is not severe. Appropriate follow-up care should be arranged in all instances because even minor spinal injuries may be associated with prolonged disability resulting from chronic pain.

For patients with minor wedge fractures (<10% wedge fractures) who do not have an associated ileus or neurologic deficit, outpatient management may be possible. However, most wedge fractures of the thoracic and lumbar spine are usually best managed in the hospital for several reasons. First, patients with these injuries usually have marked discomfort,
often requiring parenteral narcotics. Second, significant force is generally required to fracture thoracic or lumbar vertebrae, and associated intrathoracic or abdominal injuries should be considered. Finally, lower thoracic and lumbar fractures are often associated with prolonged and occasionally delayed gastrointestinal ileus, requiring continuous nasogastric suction.

### Key Concepts

- Victims of motor vehicle crashes, falls from heights, and sports-related injuries should have their entire spines examined for evidence of injury. Spinal radiographs should be obtained in the presence of suggestive symptoms or signs, or when an abnormal mental status or distracting injuries hamper clinical assessment.
- In order to prevent inadvertent movement of the spinal column, spinal precautions should be maintained in patients with altered mentation until the presence of a spinal injury can be excluded either clinically or radiographically.
- Evidence that high-dose methylprednisolone is a clinically efficacious intervention in the management of acute blunt partial SCI is lacking, and because of the possibility of severe side effects, its use can only be considered, at best, an option.

Neck trauma can result in a spectrum of injuries and complications ranging from incidental to life-threatening, including hemorrhagic shock, acute neurologic injury, and airway obstruction. Vascular and laryngeal injuries can rapidly compromise the airway, challenging the most experienced physician. Stable-appearing patients can harbor insidious injuries associated with high morbidity and mortality if not recognized and treated in a timely manner. Practicing emergency physicians not only must be familiar with the spectrum of injuries and subtle presentations associated with neck trauma but also should be well versed in neck anatomy, diagnostic evaluation, management controversies, and airway salvage techniques.

Neck trauma is divided into three major mechanisms: blunt, penetrating, and strangulation or near hanging. The injuries caused by these mechanisms can be further categorized into injuries of the airway (laryngotracheal), digestive tract (pharyngoesophageal), vascular system, and neurologic system. Each of these injuries has unique features and is discussed separately.

Principles of Disease

Pathophysiology

Penetrating Trauma

The incidence of penetrating neck trauma is reported to be 0.4 to 5% of all traumatic injuries and typically results from one of three major mechanisms: gunshot wounds (GSWs), stab wounds, and miscellaneous injuries that include impalement and shrapnel wounds. GSWs are further divided into high-velocity and low-velocity injuries. High-velocity missiles include military-style weapons and hunting rifles that can achieve bullet velocities of 2200 to 3200 feet/second or greater. These missiles can easily penetrate soft tissue or bone; their pathway is generally direct and predictable unless deflected, although they can also cause remote injuries through a blast effect. Bone penetration requires a minimum velocity of 350 feet/second. Low-velocity injuries (small-caliber handguns and air guns) are caused by missiles that travel at significantly slower velocities (e.g., 300 feet/second for .22-caliber pistols). Slower moving missiles tend to produce erratic pathways, often demonstrating no direct relationship to the entrance or exit wounds. Blast or cavitation effect pertains mainly to higher velocity missiles (>1000 feet/second). Cavitation refers to the immediate release of kinetic energy as the bullet enters the tissue. This energy release causes temporary displacement of the surrounding tissue with cavity formation along the bullet’s pathway. Cavitation can cause extensive soft tissue damage beyond that caused directly by the bullet.

The neck zone and mechanism of injury should be noted because lower energy injuries (knife, handgun, or long-range birdshot or buckshot) cause a 50% lower incidence of clinically significant lesions (Fig. 41-1). Zone I and III injuries pose a greater surgical challenge, and clinicians are more likely to order preoperative diagnostic tests to determine the best surgical approach (Table 41-1).

Stab wounds, being of very low velocity compared with missiles and most often limited to one side of the neck, are more amenable to nonsurgical management. Miscellaneous penetrating neck wounds can occur from any object capable of impalement, puncture, or laceration but most often result from glass fragments after motor vehicle crashes or from dog bites. The overall mortality rate for penetrating neck injuries is 2 to 6%, and the leading cause of immediate death is exsanguination.

Blunt Trauma

Blunt neck trauma most frequently results from motor vehicle crashes but can occur after assaults, “clothesline” injuries, strangulation, and sports injuries. Blunt vascular injuries are rare but represent some of the most underdiagnosed injuries seen by emergency physicians and trauma surgeons. Blunt injuries to the aerodigestive and vascular tracts are uncommon compared with penetrating injuries but can cause acute airway compromise and delayed complications.

Anatomy

The neck is a complex, closed anatomic area dense with vital structures and invested with fascia creating several compartments. Because of this close anatomic relationship, vascular injury with hemorrhage either can be tamponaded by fascial planes and neighboring structures or can cause marked anatomic distortion, making evaluation and airway management extremely difficult. Two methods are used to describe the external neck: zones and triangles. Anatomically, the neck has been divided into triangles (anterior and posterior). The anterior triangle is laden with vital structures (neurovascular...
and aerodigestive tracts) and is bordered anteriorly by the midline, posteriorly by the sternocleidomastoid muscle, and superiorly by the lower edge of the mandible. The posterior triangle is located within the boundaries of the sternocleidomastoid muscle anteriorly, the clavicle inferiorly, and the anterior border of the trapezius muscle posteriorly. Excluding spinal trauma, injury to this region often has a more favorable prognosis because of the relative paucity of vital structures.

Current practice favors division of the neck into zones I, II, and III. This division has both anatomic and management implications for penetrating neck trauma. Zone I (base of neck) extends superiorly from the sternal notch and clavicles to the cricoid cartilage. It comprises the thoracic outlet below the cricoid cartilage. Injury to this region can affect both neck and mediastinal structures. Zone II (midneck) is the area between the cricoid cartilage and the angle of the mandible. Zone II injuries are therapeutically distinct because they lie in the most exposed region of the neck, making these injuries accessible to direct surgical visualization with easier proximal and distal vascular control. Zone III (upper neck) extends from the angle of the mandible to the base of the skull. As with zone I injuries, proximal and distal vascular control in this region is difficult to achieve (Box 41-1).

Two fascial layers, the superficial fascia and the deep cervical fascia, cover neck structures. The superficial fascia covers the platysma muscle and is located just below the skin. The deep cervical fascia is divided into three parts: The investing layer surrounds the neck and splits to encase the sternocleidomastoid and trapezius muscles; the pretracheal layer adheres to the cricoid and thyroid cartilages and travels caudally behind the sternum to insert on the anterior pericardium; and the prevertebral layer envelops the cervical prevertebral muscles and extends to form the axillary sheath, which covers the subclavian artery. The pretracheal layer is clinically important because of its connection from the neck to the anterior mediastinum. Missed aerodigestive injuries can result in mediastinitis because of this anatomic continuity. The carotid sheath is made up of portions from all three divisions of the deep cervical fascia. The platysma muscle, sandwiched between the superficial and deep cervical fascia, covers the anterolateral neck. It has clinical significance because of its superficial location and proximity to vital structures. If the platysma muscle is violated, injury to these structures should be suspected. Examination of any penetrating neck wound should document the zone or

zones of injury and presence of platysma violation without Blind probing is discouraged as it may dislodge a clot and induce major hemorrhage.9

**CLINICAL FEATURES**

Patients with neck injury can manifest numerous signs and symptoms, but most are nonspecific. This makes diagnostic strategies difficult, especially in the stable patient. Much debate in the current literature centers on the safest and most cost-effective approach to evaluating patients with possible neck injury. Serial examinations are crucial, searching for evidence of progressive airway or vascular compromise. Features that suggest decompensation in a previously stable patient can include dyspnea, dysphonia, stridor, drooling, expanding hematoma, bruising, cerebral ischemia, or shock.

**DIAGNOSTIC STRATEGIES**

The reliability of physical examination, coupled with ancillary studies, in detecting serious neck injury in a stable patient is becoming less controversial. Researchers historically divided between those who did and those who did not believe that physical examination alone was adequate in determining which patients needed ancillary studies.9-13 A prospective study of 393 patients with penetrating neck injuries determined that 30% of patients with no physical findings subsequently had positive neck explorations.9 In contrast, a prospective series of 223 patients with penetrating neck wounds found that physical examination was reliable in determining which patients needed vascular or esophageal diagnostic studies.10 Stable patients should be evaluated for the presence of “soft” and “hard” signs of aerodigestive or neurovascular injury (Box 41-2). Most patients with hard signs benefit from surgical intervention. Controversy surfaced over the stable patient with soft or no signs of injury. Historically, management of penetrating neck trauma has undergone a similar evolution to trauma in other regions in that management has progressed from a policy of mandatory exploration to one of selective management based on ancillary studies and serial physical examination.14,15

**MANAGEMENT**

**Stable Patients**

Ideally, stable patients with neck injury should be transported to a trauma center. Despite a stable initial appearance, airway compromise can ensue rapidly and intervention is essential at the first sign of airway distress. Necessary interventions should be initiated during transport to the emergency department rather than at the scene to avoid delays in definitive care. Open wounds should be covered and sufficient compression applied to control bleeding and prevent air embolus without occluding the airway or blood flow to the brain. Consideration of cervical spine damage, especially in the face of blunt trauma, or in the presence of neurologic deficits should prompt the application of a cervical collar.

**Unstable Patients**

Airway management must be the highest initial priority in the unstable patient. Cervical spine immobilization is typically unnecessary in penetrating neck trauma unless the patient has coexistent blunt trauma or evidence of a spinal cord injury. Oral intubation using rapid sequence intubation (RSI) is considered safe in most patients with neck trauma.16,17 When the airway has been stabilized, breathing assessment is standard, with consideration of the associated risk of hemothorax or pneumothorax, seen primarily with penetrating zone I injuries. Caution is required when bag-valve-mask ventilation is necessary because air can be forced into injured tissue planes, resulting in massive subcutaneous emphysema and subsequent airway distortion or, rarely, air embolus. Active bleeding sites or wounds with blood clots should not be probed because massive hemorrhage can ensue. Ideally, bleeding is controlled by direct pressure. Blind clamping of active bleeding sites should be avoided because of the high concentration of neurovascular structures in the neck. If a vascular injury is suspected, mild Trendelenburg’s position is recommended to reduce the risk of air embolism. Intravenous access is best placed on the noninjured side, avoiding the ipsilateral neck or upper extremity until vascular injury has been excluded. Cervical collars might obscure neck pathology and preclude adequate examination. Partial removal of the collar while maintaining in-line stabilization may be necessary to perform adequate serial examinations.

The presence of profound shock or cardiopulmonary arrest unresponsive to fluids or emergency department thoracotomy should prompt the physician to consider venous air embolism (VAE). If this condition is suspected, the patient should be placed in a head-down, left lateral decubitus position to cause intracardiac air to accumulate in the apex of the right ventricle. If this maneuver alone does not improve cardiac output, aspiration of air from the apex of the right ventricle either through an ultrasound-guided pericardiocentesis needle or under direct vision after emergency department thoracotomy may be lifesaving. Evidence of cerebral ischemia, as manifested by profound alteration in consciousness, or stroke-like symptoms suggest injury to the cervical vessels or cerebral arterial air embolism.

Caution is advised in any patient with suspected vascular injury who requires a nasogastric tube (NGT). The retching typically seen with placement can dislodge a hematoma, resulting in immediate hemorrhage. If indicated, an NGT should ideally be placed after the patient is intubated. Conversely, an NGT can be therapeutic by removing gastric contents to prevent aspiration, and it can be diagnostic because a bloody aspiration implies visceral injury.
Airway Management

Orotracheal Rapid Sequence Intubation

Although the ideal airway technique for neck trauma patients has been debated during the past decade, orotracheal intubation using RSI has been shown to be safe and effective and it should be considered the first-line airway technique unless contraindications exist.16,17 Orotracheal RSI is often successful even after neck trauma with airway distortion.18 RSI has also been shown to be superior to intubation without neuromuscular blocking agents.19 However, RSI medications should be used only by an experienced intubator. Concern that complete muscle relaxation would lead to airway obstruction or that excessive movement would cause worsening of unstable cervical spine fractures has not been borne out.16,20 There are numerous alternatives for achieving intubation, but the emergency physician must be familiar with their limitations in the setting of neck trauma.21 Less commonly used airway salvage techniques, however, may diminish the emergency physician’s comfort level and prolong the airway stabilization procedure.

If the cervical spine must remain immobilized, an assistant should maintain in-line stabilization of the head and neck.22 Relative contraindications to RSI include massive facial trauma or suspected laryngeal injury. When time allows, an initial inspection of the airway can be made using a laryngoscope in the awake patient. In cases in which orotracheal intubation is expected to be difficult, an attempt to intubate over a naso- oroboeal intubation (BNTI) was the procedure of choice in the early literature, esophageal obturator airway, retrograde intubation, laryngeal mask airway, and awake endotracheal intubation are generally not used as primary procedures or airway salvage techniques in trauma patients.24,32

Miscellaneous Techniques

Other airway techniques include fiberoptic laryngoscopy and bronchoscopy, which have been used successfully for difficult airways, although excessive bleeding can render visualization difficult. Lack of experience and time constraints are cited as reasons why these techniques are not preferred in the emergency department.1,16 Emergency tracheostomy is not a common emergency department procedure because it is technically difficult and time-consuming to perform. It should be attempted only in select cases in which other techniques are contraindicated or not available. Although reported in the literature, cricothyrotomy contraindicated or not available. Although reported in the literature, cricothyrotomy, which include inadvertent catheter dislodgement result in massive subcutaneous emphysema, catheter kinking, perforation of the posterior wall of the trachea and esophagus, pneumothorax, and hypercarbia. Complete upper airway obstruction is considered a contraindication because barotraumas can result from inadequate exhalation.21,30

Pediatric Considerations

Airway management in the pediatric trauma patient tends to be more anxiety-provoking, in part because of the different anatomic considerations. Ideally, the approach to the pediatric airway is similar to that to the adult airway, using orotracheal RSI. The incidence of unstable cervical fractures in children is lower than in adults.33 As in adults, airway salvage techniques may be necessary, but fewer options are available in young children. The airway of the young child and infant is higher and more anterior, with the narrowest region of the airway at the cricoid cartilage.34 The small cricothyroid membrane and the soft, poorly mineralized pediatric larynx make cricothyrotomy contraindicated in children younger than 10 years. Emergency tracheostomy, which is a difficult procedure in young children, or transcutaneous jet insufflation may serve as a salvage technique.35 BNTI in the infant and very young child is also not recommended, in part because the smaller endotracheal tubes are too pliable to be consistently passed.

Cervical Spine

Numerous papers have been written on the safety of orotracheal intubation in patients with known or suspected cervical spine injury.19,36,37 Historically, cadaver studies generated fear of head movement during intubation, thus causing some to abandon the orotracheal route of intubation. However, RSI with in-line stabilization has not been shown to produce neurologic sequelae in humans and is believed to be a safe means of securing the airway in patients with both penetrating and blunt cervical trauma.16,35 Fear of delayed neurologic sequelae from cervical spine injury following intubation should not preclude using RSI with in-line stabilization. Neurologically intact patients with unstable cervical fractures secondary to penetrating trauma rarely manifest delayed neurologic
There is greater concern for occult or overt cervical spine injury in the patient with blunt neck or multisystem trauma, although cervical spine injuries in this population are not as common as once thought. Armed with this knowledge and barring contraindications, emergency physicians should use the airway technique with which they are most comfortable. Delays in securing an airway because of indecision regarding which technique to use can lead to hypoxic brain injury.

**Mandatory versus Selective Exploration**

The debate is ongoing in the trauma literature concerning the best way to manage penetrating neck injuries. Before World War II, patients with penetrating neck trauma were treated expectantly rather than aggressively despite unacceptably high mortality rates (18–35%). In an attempt to reduce the mortality associated with penetrating neck injuries, the concept of mandatory surgical exploration of all penetrating neck wounds was developed. Mandatory surgery drastically reduced mortality rates to 6%. Wartime experience justified the ongoing utilization of mandatory surgery in victims with penetrating neck injury, and this was widely accepted for decades.

Despite low mortality rates achieved with mandatory surgery, negative neck explorations concurrently increased 40 to 63% during the mid- to late 1900s as many institutions adopted a mandatory surgical approach. As with other traumatic injuries, an effort to reduce the negative exploration rate while maintaining low morbidity and mortality rates led to the concept of selective surgical management, which remains institution specific. Selective management offers a spectrum of approaches, ranging from serial physical examinations to an array of diagnostic tests in the stable patient. A selective approach is justified because (1) military injuries were often secondary to high-velocity missiles, as opposed to currently used weapons (e.g., knives and handguns) and animal bites; and (2) improved technology currently allows much greater accuracy in the detection of injuries. A review of zone II penetrating neck trauma cites similar overall mortality rates of 5.85% in the mandatory group and 3.74% in the selective group. Current literature favors a selective approach, with the trend in the past decade being to minimize invasive procedures.

**Transcervical Gunshot Wounds**

Transcervical gunshot wounds (TC-GSWs) represent a subset of penetrating neck trauma and are included in the debate between mandatory and selective management schools. TC-GSWs are associated with a twofold increased incidence of injuries compared with GSWs that do not cross the midline (79 vs. 31%). The most common injury seen is vascular (48%), followed by spinal cord (24%). Although some centers still practice mandatory exploration for these injuries, prospective studies suggest that stable patients with TC-GSWs can be safely evaluated using a selective surgical approach with the appropriate diagnostic studies and frequent serial examinations. GSWs in the anterior midline also involve an increased incidence of vascular and visceral injuries, and a more aggressive diagnostic approach should be considered in these patients.

**DISPOSITION**

Many patients who present to the emergency department with penetrating or blunt neck trauma have predetermined disposition, especially when their condition warrants further diagnostic studies, surgery, or intensive care. Most stable patients should be admitted for observation. All patients with platysma muscle violation should be admitted to the surgical service for ongoing observation, regardless of their stability. Careful observation should be maintained for patients with blunt neck injury because they can manifest delayed signs and symptoms of viscerovascular injury with serious consequences.

Because smaller hospitals may have neither the ancillary support nor the personnel to perform serial bedside examinations, mandatory exploration might be in the patient’s best interest in these facilities. Level I trauma centers generally have sufficient ancillary support and diagnostic tools and are more suited to avoid surgery safely in stable patients. Studies suggest that surgeons with trauma experience tend to perform fewer neck explorations.

**SPECIFIC INJURIES**

**Pharyngoesophageal Trauma**

**Epidemiology**

Esophageal injuries are infrequently reported after penetrating neck trauma, representing only 0.11% of all trauma admissions. Blunt esophageal perforation is even less common, with only 10 case reports in the literature before 1990. The low incidence of injury most likely results from the relatively protected position of the esophagus. The cervical esophagus is injured more often than the distal segment. Mortality from esophageal injuries has remained relatively high during the past two decades, with an overall rate of 19–22%.

**Pathophysiology**

Early diagnosis of esophageal injury is crucial because spillage of orogastric contents with bacterial contamination leads to florid inflammation, infection (abscess and mediastinitis), and death. Esophageal injuries represent the most frequently missed injuries in the neck and may be the leading cause of delayed death resulting from neck trauma.

**Clinical Features**

Although there are no pathognomonic signs of esophageal injury, soft signs of injury include hematemesis, odynophagia, subcutaneous emphysema, and blood in the saliva or NGT; the presence of these should increase concern for esophageal injury. Other associated findings include dyspnea, hoarseness, stridor, cough, pain and tenderness in the neck, and resistance to passive neck movement.

Physical examination has been shown to be unreliable in diagnosing esophageal injury, with an accuracy of only 72%. Because timely diagnosis is very important, most believe that sole reliance on physical examination is not warranted in stable patients with soft signs of esophageal injury.

**Diagnostic Strategies**

Unfortunately, esophageal injuries are difficult to diagnose. To compound this, delays in diagnosis and thus treatment are strongly associated with adverse outcomes. Inherent delays in diagnosis and operative repair are believed to contribute to the increased morbidity and mortality seen with these injuries; however, it is not known what constitutes a safe delay. Because of diagnostic difficulty seen with digestive tract injuries, proximity wounds should prompt an aggressive search...
for an esophageal injury. Timely diagnosis is believed to be associated with decreases in morbidity and mortality, but this time frame has yet to be defined. 47,48

Diagnosing esophageal injury often depends on more than a high clinical suspicion. Contrast esophagography is considered relatively unreliable for diagnosing esophageal injuries, with a sensitivity of 80 to 89%. 41,46 This study requires adequate views for accurate interpretation and thus requires the patient’s cooperation. Flexible endoscopy has been reported as insensitive, primarily missing proximal esophageal injuries because the scope is unable to efface the mucosa in this region as can a rigid endoscope. 3 The combination of rigid esophagoscopy and contrast esophagography is much more sensitive, but the former requires general anesthesia. Currently, the combination of contrast swallow and flexible endoscopy appears to be accurate in diagnosing esophageal injuries, yielding a sensitivity of 100%. 46 Despite the selective management options mentioned, a prospective study suggested that only obtunded or symptomatic patients (hematemesis, painful swallowing, or subcutaneous emphysema) need studies to exclude esophageal injuries. 10 Plain films of the neck and chest radiographs suggest esophageal perforation if pneumomediastinum or retropharyngeal air is present. 48,49 Many agree that only select populations should undergo a watch-and-wait approach and that the vast majority of patients with suspected esophageal injury need definitive diagnosis and treatment. 49

With the advent of the higher resolution computed tomography (CT) scan, there has been a controversial suggestion that high-speed, thin-cut CT scanning may increase the sensitivity for penetrating zone II esophageal injuries and either supplement the physical examination in select patients or negate the need for other diagnostic studies. 50 However, sole reliance on this diagnostic modality is currently not supported by the literature when searching for esophageal injuries. CT scan can be useful to look at the wound track or trajectory of a bullet in the instance of penetrating trauma, thus helping to determine if a proximity wound is likely, but it has not been shown to be sensitive as a stand-alone diagnostic modality. 51,52

Management

When esophageal injury is suspected, broad-spectrum antibiotics with anaerobic coverage should be administered, and the patient should receive nothing by mouth pending surgical exploration. Preoperative placement of an NGT with suction may reduce the spillage of gastric contents into the wound.

Laryngotracheal Trauma

Mechanisms of Disease

Laryngotracheal (LT) injuries account for less than 1% of all trauma injuries, with most confined to the cervical trachea. Most LT injuries result from direct blunt force sustained in motor vehicle crashes, in which the extended neck strikes the steering wheel or dashboard and the larynx is compressed between the fixed object and the cervical spine. Other mechanisms leading to LT injuries include clothesline injuries, improperly fitting shoulder harnesses, near hanging, assaults, athletic events, attempted strangulation, and iatrogenic wounds. Penetrating LT injuries comprise 10% of all penetrating neck trauma. 3 Associated cervical spine injuries should always be considered simultaneously, especially when evaluating a patient with blunt neck trauma.

The cricoid cartilage is the only complete solid ring in the larynx. Fractures of the cricoid cartilage can lead to death through acute airway obstruction and are the most serious laryngeal injuries. Calcification of the laryngeal cartilages begins during the teenage years, and fractures before this age are much less likely to appear on plain neck films. The degree of airway obstruction after blunt trauma to the larynx is inversely related to the degree of cartilage calcification, putting children at highest risk.

Clinical Features

There is no consensus on whether all surgically significant LT injuries will present clinically at the time of initial evaluation in the emergency department. 20,21 Bubbling or air leakage from a neck wound should signal injury to the respiratory tract and is considered a hard sign of LT injury. Massive subcutaneous air and bony crepitus over the larynx suggest LT injury, as does a clothesline mechanism. 54 Other clinical features of LT injury include dysphonia, aphony, dyspnea, stridor, hemoptysis, subcutaneous emphysema, laryngeal crepitus, neck tenderness or pain over the larynx, a visible neck wound, or loss of anatomic landmarks secondary to hematoma. Pain with tongue movement implies injury to the epiglottis, hyoid bone, or laryngeal cartilage. 1 In one study, dyspnea and stridor were the most common signs of injury in children with LT trauma. 55 Others cite subcutaneous air found by examination or on radiographs and tenderness over the larynx or trachea as the most common findings. 56

Diagnostic Strategies

Diagnostic evaluation options exist for the stable patient. Missed injuries can lead to long-term sequelae, including voice change, dysphagia, laryngeal stenosis, and chronic pain. Patients with penetrating trauma are managed by a mandatory or selective protocol. Plain radiographs should be evaluated for extraluminal air, edema, foreign bodies, and fracture of the cartilaginous laryngeal structures. Laryngoscopy or flexible nasopharyngoscopy allows direct evaluation of laryngeal integrity. With appropriate local anesthesia, laryngoscopy is well tolerated by most patients who remain in cervical spine immobilization, and it can detect hypopharyngeal tears. Rigid endoscopy is useful to evaluate injury distal to the larynx but requires general anesthesia. 57

Spiral CT scanning is a valuable adjunct, quickly providing detailed information about laryngeal integrity and the surrounding region. 51 CT is useful for detecting fractures of the hyoid bone, disrupted laryngeal or tracheal cartilages, significant exolaryngeal or endolaryngeal hematoma, and dislocations of the cricothyroid or cricoarytenoid joints and also for assessing vocal cord integrity and airway lumen diameter. Despite these advantages, CT has limitations and should not be relied on to detect mucosal perforations, degloving injuries of the cartilage with denuded mucosa, and certain types of LT separation. CT is not exclusively utilized in penetrating neck trauma and may be less helpful when evaluating poorly calcified pediatric cartilaginous structures because these fractures can be more difficult to visualize.

Widespread access to ultrasound has led to an increase in its use for trauma patients. Some advocate ultrasound to detect blunt laryngotracheal injuries such as laryngotracheal separation; however, larger studies are needed to confirm the utility of this modality. 20 CT is a good primary tool to assess for LT injury. Direct visualization via endoscopy can provide additional information in select cases where mucosal injury is likely and surgical exploration is not immediately indicated.

Management

Airway compromise in patients with LT trauma can be immediate or delayed. Clinical judgment must be exercised in
patients who initially appear to have stable, patent airways if they are to be sent to other departments for further diagnostic testing. Delayed airway occlusion can be rapid and life-threatening, and these patients require close monitoring. Airway management controversies persist, and the question regarding the safest technique for intubation (otracheal, cricothyrotomy, tracheostomy, fiberoptic scope, or adjuncts) is unresolved. Otracheal intubation can complete a partial LT separation or create a false passage. Likewise, cricothyroidotomy can further damage an injured larynx. If complete LT separation is present with distal retraction of the trachea, otracheal intubation is likely to be unsuccessful, and tracheostomy might unknowingly be performed proximal to the tracheal segment. Tracheostomy in these cases is best done at the fourth or fifth tracheal ring to avoid the larynx. Because blunt LT injuries are often seen in association with multisystem trauma, they can be easily overlooked when other overt injuries are present, but these injuries in association with the need for emergent airway stabilization portend a higher mortality.

Vascular Trauma

The great vessels of concern in the neck include the carotid, subclavian, and vertebral arteries and the internal and external jugular veins. Injury to these vessels can produce morbidity and mortality through exsanguination, hematoma expansion with subsequent airway distortion and compromise, direct vessel injury leading to vascular occlusion, or embolization of a foreign body (e.g., shotgun pellet to brain or heart). Carotid artery dissection may follow even trivial neck trauma and can result in stroke in young, otherwise healthy patients. The presence of delayed-onset, evolving central neurologic deficits in a patient with neck trauma should prompt assessment of the carotid arteries for dissection. Combined data from 16 studies of penetrating neck trauma during a 25-year period found that the carotid artery was the most commonly injured artery with an incidence of 6.7%. This was followed by subclavian artery injuries (2.2% incidence) and vertebral artery injuries (1.3%).

Epidemiology

Penetrating Injury Vascular injuries represent 25% of all penetrating neck wounds, and mortality rates range from 10 to 50%. GSWs are more likely to be associated with hard signs of vascular injury than are stab wounds. Hard signs of vascular injury include pulsatile bleeding, rapidly expanding hematoma, bruit, or focal neurologic deficits consistent with carotid or vertebralbasilar arterial occlusion. Exsanguination from vascular injuries is the most common cause of immediate death after penetrating neck trauma. The jugular vein is the most frequently injured vessel in the neck, although the common carotid artery is the most frequently injured artery (22% of all cervical vascular injuries). The vertebral artery is injured in only 1.3% of all cases. Vertebrobasilar arterial injuries may follow relatively minor trauma, such as chiropractic neck manipulation, but most commonly occur in association with fractures of the spinal column. They typically arise after a delay of hours to months with signs of posterior circulation embolus or infarction, and they portend a poor prognosis.

Blunt Injury Three to 10% of all carotid injuries result from some form of blunt trauma, but blunt carotid injuries affect only 0.08 to 0.33% of all blunt trauma victims. Mortality rates for blunt cervical vascular injuries range from 20 to 40%. Blunt cervical vascular injuries are rare, and until the mid-1990s, only 480 cases had been reported in the literature. Because the internal carotid artery is the most frequently injured artery, many studies use blunt vascular and carotid artery injuries synonymously, although the vertebral artery is injured in up to 20% of cases. The actual incidence of blunt vascular injuries may be higher because of asymptomatic cases and difficulties in making the diagnosis. Blunt vascular injury should be suspected in patients with flexion-extension mechanisms, neck seat belt sign, diffuse axonal brain injury, midface, mandibular, or basilar skull fractures.

Pathophysiology

Penetrating Injury Most cases of penetrating trauma in adults are caused by knife or bullet wounds. Vessel damage most often results from direct injury, although the blast effect can cause intimal injury without directly striking the vessel, making the vascular insult similar to that seen with blunt trauma. Some centers routinely obtain angiographic studies of all significant neck wounds; others restrict angiography to zone I and zone III injuries. In the past decade, reliance on CT angiography (CTA) has become increasingly common. Zone I injuries in particular can harbor clinically occult arterial injuries, and routine preoperative arteriography has been historically advocated to detect injury and facilitate a judicious surgical approach when positive. Likewise, zone III vascular injuries can be exceedingly difficult to approach surgically, and thus some surgeons still prefer preoperative CTA followed by exploration for any positive or equivocal findings. Many surgeons believe that preexploratory vascular studies are noncontributory in zone II injuries and may lead to delays in definitive care because these lesions are easily approached surgically.

Blunt Injury Blunt trauma to the cervical vessels can result in a spectrum of arterial injuries, including intimal tears, thrombosis, dissection, and pseudoaneurysm. Embolization can occur from a thrombus that develops at the injury site. The most common mechanism for blunt internal carotid artery injury is sudden, forceful hyperextension and lateral rotation of the neck. This mechanism can cause stretching of the carotid artery over the transverse processes of the upper cervical vertebrae, resulting in intimal injury. Other mechanisms responsible for this type of injury include direct blunt force to the side of the neck, intraoral trauma (e.g., children falling on lollipops), and basilar skull fractures, which have rarely been associated with injury to the intracranial portion of the carotid artery. Blunt carotid artery injuries most often result from motor vehicle accidents but have also been reported after fights, athletic events, seat belt injuries, clothingline injuries, and near hangings. Seat belt signs on the neck may suggest insidious vascular injury, but a review of 131 patients with a seat belt sign at the neck found that only 0.76% had a significant vascular injury.

Clinical Features

The debate regarding whether the physical examination is sensitive enough to detect vascular injuries in stable patients with minimal signs and symptoms is unresolved. Angiographically documented arterial injuries have not been reliably detected by physical examination in some series. Others argue that although discrepancies may exist, they are not clinically relevant in the asymptomatic patient and rarely change management, and thus they conclude that serial examinations are adequate. Signs and symptoms of vascular injury include pulsatile hematoma, bruits, pulse deficit, hemothorax, airway compromise (from hematoma expansion), shock, and neurologic deficits.

Delayed presentation of a vascular injury is most often neurologic in nature, with symptoms ranging from transient
ischemic attack (TIA) to global cerebral ischemia. Horner’s syndrome has been associated with vascular injury, particularly carotid artery dissection.67 Delays in the onset of neurologic sequelae of weeks to years have been reported. TIA’s usually result from release of small emboli from the injured vessel, which can herald the onset of a profound deficit. Thus, any focal neurologic abnormality should prompt the emergency physician to include vascular injuries in the differential diagnosis, especially after a normal head CT scan.

Because they are rare or delayed in their presentation, blunt vascular lesions are often not considered initially. Other injuries can divert the emergency physician’s attention to more immediately life-threatening wounds. Diagnosis is also often delayed because 17 to 35% of patients do not develop neurologic symptoms for more than 24 hours.68 Drugs, alcohol, or head trauma can further obscure or contribute to delays in the diagnosis of blunt vascular injury. Because of the low incidence of blunt vascular injuries, no large prospective study has fully defined the “at-risk” patient.

Diagnostic Strategies

There is also controversy regarding how aggressive the search should be for vascular injuries using surgical exploration or other diagnostic modalities in the patient with minimal symptoms. Blunt cervical vascular injuries represent some of the most underreported injuries because of their insidious presentation but ultimate association with a catastrophic neurologic outcome.

Conventional arteriography has been used extensively to detect vascular injury in patients with both blunt and penetrating injuries. A four-vessel arteriogram is time-consuming and expensive but historically felt to be helpful in planning the best surgical approach. The majority of patients require four-vessel studies, although occasionally a two-vessel (ipsilateral carotid and vertebral) arteriogram may be warranted if the injury is isolated to one side of the neck.1 If ordered, these contrast studies should include the intracranial portion of the carotid artery with zone III injuries or suspected blunt cervical trauma. Zone I injuries should include the aortic arch with its branches. Although controversial, some still consider angiography as the “gold standard” for diagnosing vascular injuries69; if the study is negative, many recommend nonsurgical management when aerodigestive injuries have been excluded. Despite a sensitivity and specificity of nearly 100% and a complication rate of less than 2% for arteriography, other, less invasive diagnostic tests have been evaluated for accuracy, speed, cost, and efficacy.70

Duplex ultrasonography has been used in combination with or instead of arteriography to exclude cervical vascular injury in patients with both penetrating and blunt trauma.71 Despite clinical success, limitations of ultrasonography include the risk of missing zone I and zone III injuries and the lack of 24-hour availability at many centers. Whether duplex scanning can reliably detect pseudoaneurysms or intrathoracic, distal internal carotid, and vertebral artery injuries remains unproved. Also, some patients must remain in cervical spine protection, limiting neck manipulation necessary for optimal views. Many surgeons are not comfortable with serial duplex examinations as a means of detecting traumatic vascular lesions and continue to use arteriography as the mainstay of diagnosis.

With the advent of newer generation machines, CTA (CT angiogram with 64-slice or more) has largely replaced conventional angiography. Part of the attraction is that they are rapid, readily available, and accurate.72-74 CTA allows for the detection of many types of vascular injuries, and it characterizes cervical soft tissues, cervical vertebrae, and spinal cord as well as aerodigestive structures. Increasingly, more centers rely on CTA when no clear surgical indications are apparent, although CTA can potentially miss lethal lesions, such as pseudoaneurysms. Centers that prefer a selective approach are increasingly reporting success with this modality in the face of platysma violation.75 Magnetic resonance angiography (MRA) has also been reported to be helpful despite high cost and lack of 24-hour availability.76 MRA has additional distinct disadvantages that include remote location in many centers, contraindication if metallic foreign body (bullet fragments), and inability to directly visualize the neck during the procedure for expanding hematoma. Because neither CTA nor MRA has consistently proven to have the arteriogram’s high degree of accuracy for detecting blunt or penetrating vascular injuries, they should not be relied on solely at the exclusion of proven diagnostic modalities.

Head CT scans are often ordered in response to ischemic neurologic deficits because many suspect closed-head injury initially. When these symptoms result from traumatic occlusion or dissection of the carotid artery, the head CT scan is frequently normal because the ischemic changes are often not obvious for more than 24 hours. Any unexplained focal or hemispheric neurologic deficits should prompt the emergency physician to consider vascular injuries.

Although not indicated in most cases of suspected vascular injury, plain films can occasionally be useful. Anteroposterior and lateral neck films can help determine a bullet trajectory by comparing the entrance wound with the location of the foreign body, if present. Chest radiographs allow evaluation of the mediastinum and identification of hemothorax or pneumothorax.

Management

Blunt Injury Treatment options for blunt artery injuries depend in part on the mechanism and type of injury and location of the lesion. Treatment modalities include surgery, anticoagulation, and observation. Anticoagulation, antithrombotic therapy, and endovascular stenting have all been successful treatments in the long-term treatment of blunt vascular injuries, although heparin is the preferred treatment in the acute phase for carotid artery dissection absent any major contraindications.77 Others have not found heparin to be beneficial.62 Antiplatelet therapy has been suggested for carotid artery dissection to prevent clot propagation.60 Because of possible complications, none of these treatment modalities should be initiated without appropriate consultation. Surgical treatment includes ligation, resection, thrombectomy, and stent placement.1,62

Penetrating Injury The ideal management strategy for injuries of the vascular system resulting from penetrating trauma has not been determined. Because many of these patients are young with anticipated “clean” carotid arteries, some surgeons routinely attempt surgical repair. Because of concern that reperfusion might convert an ischemic infarction to a hemorrhagic infarction in patients with profound neurologic deficit, others prefer ligation over repair in a select population of patients.

Venous Air Embolism VAE is a subset of vascular injuries that can lead to life-threatening complications if not detected. VAE has been reported after blunt, penetrating, and iatrogenic mechanisms. VAE occurs when air enters the injured vessel, usually during inspiration, resulting in distal vascular occlusion and infarction. In any patient with a suspected major venous injury, direct pressure should be maintained over the wound while the patient is kept in the Trendelenburg position. Autopsy reports on trauma victims reveal air in both the right
side of the heart and the pulmonary artery. When standard treatment fails in a pulseless trauma patient, VAE should be immediately suspected and the right ventricle aspirated for air after the aorta is cross-clamped. Rarely, air embolism has been reported with arterial injuries as well.1

Nervous System

When evaluating any patient with neck trauma, the examiner must remember that the brachial plexus, peripheral nerve roots, cervical sympathetic chain, and cranial nerves VII, IX, X, XI, and XII are vulnerable, as well as the spinal cord. Neurologic deficit can also result from vascular injury with subsequent cerebral ischemia. Complete cord injury can result in spinal (neurogenic) shock with paraplegia, bradycardia, and hypotension. Brown-Séquard syndrome (hemisection of the spinal cord) arises with ipsilateral hemiplegia and contralateral sensory deficit. Brachial plexus, spinal root, and peripheral nerve injuries have been reported after neck trauma and can result in both sensory and motor deficits. Phrenic nerve injury may compromise spontaneous respiration by causing ipsilateral diaphragmatic paralysis. Hoarseness can result from direct laryngeal trauma, but injury to the recurrent laryngeal nerve, which branches off the vagus nerve (cranial nerve X), should also be suspected, with vocal cord paralysis on the affected side.

Thoracic Duct, Glandular, and Retropharyngeal Injuries

Other, less common injuries have been reported in association with neck trauma with variable signs and symptoms. Thoracic duct injuries are less likely to be apparent initially and are frequently diagnosed intraoperatively or after development of a chylothorax. Glandular wounds, including those of the thyroid, parathyroid, and salivary glands, are reported rarely. Retropharyngeal hematomas are also extremely rare but can result in life-threatening airway compromise.1,78

Near Hanging and Strangulation

Epidemiology

Hanging and strangulation represent the second most common form of suicide in the United States after firearm use.79 The number of deaths from suicidal hanging is increasing.80 Approximately 5330 strangulation deaths occur annually in the United States.81

The terms hanging and strangulation are often used interchangeably, with hanging being a subset of strangulation. Hanging is categorized as judicial (complete hanging) or nonjudicial (incomplete hanging). Complete hanging refers to the presence of a ligature around the victim’s neck and a subsequent drop resulting in the victim being freely suspended. In contrast, incomplete hanging refers to the partial suspension of the victim’s body with some part still in contact with the ground. Judicial hanging victims classically fall at least the height of their body, whereas incomplete hanging is more likely to be seen in confined spaces (e.g., homes and jail cells), where a fall from height resulting in full body suspension is less possible. On the basis of the location of the ligature knot, hanging is further divided into atypical and typical categories. Typical hanging refers to the knot being midline directly under the occiput, which leads to a higher likelihood of complete arterial occlusion. Atypical hanging refers to all other knot placements.82

Manual strangulation and ligature strangulation refer to external compression of the neck, usually by hands or ligature, but independent of the weight of the victim. Postural strangulation, generally seen in the younger pediatric population, refers to death sustained by the victim’s body weight compressing the anterior neck against a firm object.83

Pathophysiology

Judicial hanging with adequate fall distance results in forceful distraction of the head from the neck and body. This classically leads to high cervical fractures, complete cord transection, and death. Attempted-suicide hangings frequently occur at inadequate height and therefore tend to mimic nonjudicial strangulation. Cervical fractures in the latter group are rare, and no fractures have been reported in near-hanging victims.83

In essentially all types of nonjudicial strangulation, the ligature or external force initially applied causes venous congestion with stasis of cerebral blood flow leading to unconsciousness. Once the person is limp, the ligature or external force can tighten further, leading to complete arterial occlusion and ultimately to brain injury or death. Vagal reflexes resulting from pressure on the carotid body may contribute to fatal dysrhythmias, as may increased sympathetic tone from pericarditis.84

Pulmonary sequelae are frequently seen in near-hanging victims and include pulmonary edema, bronchopneumonia, and adult respiratory distress syndrome (ARDS).82 These complications are responsible for most in-hospital deaths after near hanging. Pulmonary edema occurs from one of two mechanisms. Neurogenic pulmonary edema results from centrally mediated, massive sympathetic discharge. Because it is more often seen in association with serious brain injury, neurogenic pulmonary edema has poor prognostic implications. Postobstructive pulmonary edema is generally associated with a better neurologic outcome. It is initiated by marked negative intrapleural pressure, which is generated by forceful inspiratory effort against an extrathoracic obstruction. When the obstruction is removed, the onset of pulmonary edema can be rapid and lead to ARDS.82

Clinical Features

External trauma may or may not be evident, depending on the mechanism of injury. If present, ligature marks appear as indentations around the neck, ranging from mild erythema to leather-like grooves following the course of the ligature. Fingernail scratches, abrasions, and contusions are variably present on the external neck as well. Tardieu’s spots are highly correlated with asphyxial deaths; these petechial hemorrhages are seen in the conjunctiva, mucous membranes, and skin cephalad to the ligature marks. They occur when the venous pressure rises in response to ligature tightening. Laryngeal injuries are reported in near-hanging victims. Thyroid cartilage fractures are seen in approximately 50% of all nonjudicial hanging deaths, and hyoid bone fractures occur in 20%. Cricoid cartilage fractures are rarely reported. Manual strangulation is responsible for the majority of fractures.82 Resulting laryngeal fractures are rarely clinically significant in survivors, and standard airway techniques are recommended.

Vascular injury leading to delayed neurologic sequelae after near hanging is rare but reported. It most often results from carotid intimal dissection or thrombus formation, resulting in partial or complete vascular occlusion or embolism.85 Carotid vascular studies should be considered in patients with unexplained focal or global neurologic deficits.84
Frequently, ventilatory support is indicated to maintain adequate oxygenation and ventilation in the comatose patient. The addition of positive end-expiratory pressure is often necessary, especially when pulmonary edema or ARDS develops. Aggressive resuscitation is warranted in the unconscious patient; the initial Glasgow Coma Scale score is generally not predictive of outcome. The altered or comatose patient should be assumed to have cerebral edema with elevated intracranial pressure, and cerebral resuscitation measures need to be actively initiated using standard technique.

Definitive studies providing guidelines on the management of hypoxic brain injury specifically related to near-hanging or strangulation injuries are lacking. Therefore, prudent cerebral protection measures may be interpreted from other data on this topic (and are discussed in detail in Chapter 6).

**KEY CONCEPTS**

- Neck trauma results from one of three major mechanisms: blunt injury, penetrating injury, or near hanging/strangulation.
- The leading cause of immediate death after neck trauma is exsanguination secondary to vascular injury.
- The leading cause of delayed death after neck trauma is esophageal injury. These wounds are rare, frequently insidious, and associated with high mortality rates if missed.
- Neck wounds should never be probed through the platysma muscle because massive hemorrhage or air embolus can ensue.
- Cervical collars can obscure impending airway disasters (e.g., expanding hematomas) and other signs suggestive of injury if not removed periodically to allow serial examinations.
- Unless a contraindication exists, orotracheal rapid sequence intubation is safe and effective in the hands of an experienced intubator.
- Vascular injuries resulting from blunt trauma represent some of the most underreported injuries because of their propensity for delayed neurologic sequelae.

- There is ongoing debate regarding whether physical examination is sensitive at detecting visceral or vascular injury, and the role of angiography versus serial examination is unresolved.
- Suspicion of venous air embolism should prompt direct wound pressure, occlusive dressings, Trendelenburg’s position, and, if the patient is in cardiopulmonary arrest, aspiration of air from the right side of the heart.
- Transcervical gunshot wounds are a subset of injuries with a twofold increased incidence of visceral-vascular injuries compared with injuries that do not cross the midline.
- All near-hanging or strangulation patients who are comatose or have altered consciousness may have elevated intracranial pressure, and appropriate cerebral resuscitation measures should be initiated.
- The leading cause of in-hospital death in this population is pulmonary complications (pneumonia, pulmonary edema, and ARDS).

Thoracic Trauma

Marc Eckstein and Sean O. Henderson

Epidemiology

Thoracic injury directly accounts for 20 to 25% of deaths resulting from trauma, accounting for more than 16,000 deaths annually in the United States. The most common cause of injuries leading to accidental deaths in the United States is motor vehicle collisions, in which immediate deaths are often due to a rupture of the myocardial wall or the thoracic aorta. Early deaths (within the first 30 minutes to 3 hours) resulting from thoracic trauma are often preventable. Causes for these include tension pneumothorax, cardiac tamponade, airway obstruction, and uncontrolled hemorrhage. Because these problems are often reversible or may be temporized nonoperatively, it is vital that emergency physicians be thoroughly familiar with their pathophysiology, clinical presentation, diagnosis, and treatment.

Approximately 75% of patients with thoracic trauma can usually be managed expectantly with simple tube thoracostomy and volume resuscitation. As such, initial care and disposition of these patients is usually performed by emergency physicians. Definitive care of these patients is often multidisciplinary in nature, involving trauma surgeons, cardiothoracic surgeons, and intensivists. Improvement in the understanding of the underlying physiologic mechanisms involved and the advancement of newer imaging modalities, minimally invasive approaches, and pharmacologic therapy contribute to decreasing the morbidity and mortality of these injured patients. The role of multidetector helical computed tomography (CT) scanning in the evaluation of trauma patients continues to expand. Although CT scans provide much greater diagnostic sensitivity than plain radiography, the precise indications for CT scanning for trauma patients remains unclear. Concerns regarding cost, contrast-induced nephrotoxicity, and cumulative radiation exposure to the thorax have been mounting.

Injuries to the lung parenchyma are common in severely injured patients and include contusion, laceration, or hematoma. Hemothorax and pneumothorax are also common injuries in patients with thoracic trauma. Treatment of these injuries has changed during the past decade primarily because of advances in diagnostic imaging techniques and an increased understanding of the pathophysiology.

CHEST WALL INJURY

Epidemiology

Among victims sustaining thoracic trauma, approximately 50% will have chest wall injury: 10% minor, 35% major, and 5% flail chest injuries. Chest wall injuries are not always obvious and can easily be overlooked during the initial evaluation.

Anatomy/Pathophysiology

An intact chest wall is necessary for normal ventilation. Outward expansion of the thorax by the respiratory muscles with descent of the diaphragm creates negative intrathoracic pressure. This causes passive air entry into the lungs during inspiration. Chest trauma, particularly blunt trauma, can severely disturb the physiology of respiration. Fortunately, most individuals have substantial respiratory reserve and can tolerate significant chest wall injury with adequate support.

Clinical Features

Elderly patients or those with preexisting pulmonary disease are sometimes unable to compensate for even minor chest wall trauma and therefore require closer attention. It is important to completely disrobe the patient and observe the respiratory rate, adequacy of tidal volume, and respiratory effort. Many chest wall injuries may be detected only by careful palpation of the chest wall, noting any areas of deformity, tenderness, or crepitus.

RIB FRACTURE

Epidemiology

Simple rib fractures are the most common form of significant chest injury, accounting for more than half the cases of blunt trauma. The susceptibility to rib fracture increases with age. The importance of this injury is not the fracture itself but, rather, the associated potential complications, particularly pneumothorax, hemothorax, pulmonary contusions, and post-traumatic pneumonia. Rib fractures in children signify serious trauma to the thorax and have a high incidence of underlying injury.

Anatomy/Pathophysiology

Ribs usually break at the point of impact or at the posterior angle, which is structurally the weakest area. The fourth through ninth ribs are most commonly involved. Ribs 1 to 3 are relatively protected, and ribs 9 to 12 are more mobile at the anterior end. This confers the “high” and “low” ribs relative resistance to fracture. Fractures occur more commonly in
adults than in children, and this is attributed to the relative inelasticity of the older chest wall compared to the more compliant nature of the chest wall in children.

The true danger of rib fracture involves not the rib itself but the potential for penetrating injury to the pleura, lung, liver, or spleen. Fractures of ribs 9 to 11 are associated with intra-abdominal injury. Patients with right-sided rib fractures are almost three times more likely to have a hepatic injury, and patients with left-sided rib fractures are almost four times more likely to have a splenic injury. Fractures of ribs 1 to 3 may indicate severe intrathoracic injury. The presence of two or more rib fractures at any level is associated with a higher incidence of internal injuries. Elderly patients with multiple rib fractures have a greater incidence of pneumonia and a higher mortality compared to patients younger than age 65 years. To prevent a minor injury from developing into a serious complication, these fractures should be diagnosed rapidly and treated expectantly.

**Clinical Features**

The diagnosis can be suspected clinically, with tenderness, bony crepitus, ecchymosis, and muscle spasm over the rib being the most common findings. Also, bimanual compression of the thoracic cage remote from the site of injury (barrel compression test) usually produces pain at the site of fracture.

**Diagnostic Strategies**

Although clinical impression and physical findings are sensitive, they are not specific and are therefore unreliable for making an accurate diagnosis. Chest x-ray (CXR) films often do not demonstrate the presence of rib fractures but are of greatest value in suggesting significant intrathoracic and mediastinal injuries. Although the upright posteroanterior chest radiograph has a higher yield in detecting rib fractures or their complications compared to other views, CT scans are significantly more effective than CXR in detecting rib fractures (Fig. 42-1). Rib series, expiratory, oblique, and coned-down views should not be used routinely. However, if simple rib fractures are strongly suspected or recognized on a clinical basis, there is no need to routinely obtain a CT unless other intrathoracic pathology needs to be studied.

Nonetheless, x-ray studies are often ordered, even though 50% of single-rib fractures are not seen on the initial x-ray study. A CT scan should be considered based on the mechanism of injury, physical examination, hemodynamic and respiratory parameters, abnormal findings on CXR (especially widened mediastinum), or clinical evidence of multiple rib fractures, especially of the lower ribs (which may herald a splenic or hepatic injury).

**Management**

Treatment of patients with acute rib fractures is based on adequate pain relief and the maintenance of pulmonary function. Oral pain medications are usually sufficient for young and healthy patients. Continuing daily activities and deep breathing should be stressed to ensure ventilation and prevent atelectasis. It is helpful to advise patients to take their pain medications and wait 30 to 45 minutes before performing deep breathing exercises, perhaps with an incentive spirometer. Pain relief must be effective or patients will not maintain activity. Binders, belts, and other restrictive devices should not be used because although they can decrease pain, they also promote hypoventilation with subsequent atelectasis and pneumonia.

The greater the number of fractured ribs, the higher the mortality and morbidity rates. Patients with three or more fractured ribs, despite the lack of other traumatic injuries, should likely be hospitalized to receive aggressive pulmonary therapy and appropriate effective analgesia. Elderly patients with six or more fractured ribs should be treated in intensive care units due to high morbidity and mortality. Older patients will probably require narcotic preparations, but care should be taken to avoid oversedation.

Multiple rib fractures in trauma patients are associated with significant morbidity and mortality. Intercostal nerve blocks with a long-acting anesthetic such as bupivacaine with epinephrine may relieve symptoms up to 12 hours with excellent results. This consists of administering 1 or 2% lidocaine or 0.25% bupivacaine along the inferior rib margin several centimeters posterior to the site of the fracture. One rib above and one rib below the fractured rib must also be blocked to obtain optimal analgesia. Other alternatives for hospitalized patients include patient-controlled analgesia, nebulized morphine, and thoracic epidural analgesia.

**Clinical Course**

Most rib fractures heal uneventfully within 3 to 6 weeks, and patients should expect a gradual decrease in their discomfort during this period. Analgesics are usually necessary during the first 1 or 2 weeks. However, in addition to the complications of hemopneumothorax, atelectasis, and pneumonia, rib fractures can result in post-traumatic neuroma or costochondral separation. These unusual complications are painful and heal slowly. Special attention should be paid to patients with displaced rib fractures, who may sustain delayed hemorrhage and death. These are typically intercostal artery tears that clot off and then rebleed.

**STERNAL FRACTURE**

**Epidemiology**

Sternal fractures and dislocations are caused primarily by anterior blunt chest trauma, usually from automobile collisions when the chest strikes the steering wheel. Risk factors for sternal fracture from blunt trauma include types of vehicular passenger restraint systems and patient age. Restrained passengers are more likely than unrestrained passengers to suffer sternal fracture. In fact, the rate of occurrence of sternal frac-
tures has increased threefold since the use of across-the-shoulder seat belts became widespread.

Anatomy/Pathophysiology

Sternal fracture usually results from the diagonal strap of a seat belt restraining the upper part of the sternum. During rapid deceleration from a frontal impact, the forward thrust of the body against the fixed seat belt across the sternum results in a fracture at that location. The location of the sternal fracture varies depending on the position of the belt, patient size, the magnitude of the impact, and the vector of the forces.

Similarly, depending on patient age, the likelihood of sternal fracture is variable. In general, sternal fractures are more common in older patients than in younger patients, and they are slightly more common in women than in men. It is believed that the more elastic and pliable chest wall of younger people allows more efficient transmission of kinetic energy to the underlying mediastinum. Although skeletal injury is less likely to occur in younger patients, damage to soft tissue structures underneath is greater. In older patients, the energy of impact is dissipated in the sternum, resulting in fewer intrathoracic injuries but a higher frequency of sternal fractures. Severe multiple rib fractures and lung contusion are concomitant injuries in more than 10% of diagnosed sternal fractures.

The natural history of a nondisplaced sternal fracture is contrary to intuition. It had been thought that the magnitude of the forces required to fracture the sternum would be associated with significant trauma to the mediastinal structures. However, isolated sternal fractures are relatively benign, with low mortality (<1%) and low intrathoracic morbidity. Cardiac complications, such as myocardial contusion, occur in 1.5 to 6% of cases. There is no association between sternal fracture and aortic rupture. Spinal fractures are seen in less than 10% of cases and rib fractures in 21%. Although sternal fractures may occur in the context of major blunt chest trauma, the presence of a sternal fracture does not imply other major life-threatening conditions. However, associated mediastinal injuries should be considered.

Mediastinal hematomas, whether or not they are related to aortic injuries, can be life-threatening. The dual problem of acute blood loss and sudden alterations in cardiopulmonary physiology can result in hemodynamic deterioration. In addition to circulatory collapse from exsanguination, mediastinal hematomas can cause death from compression of adjacent structures.

Clinical Features

Sternal fractures typically present with anterior chest pain, point tenderness over the sternum, ecchymosis, soft tissue swelling, or palpable deformity. These findings together with the history can often lead to the diagnosis.

Diagnostic Strategies

Most sternal fractures are transverse, and a lateri radiographic view is often diagnostic. These fractures can be missed radiographically because a lateral plain CXR film is not usually obtained during the initial trauma evaluation. Furthermore, plain films are sometimes inconclusive. Even if the sternal fracture is diagnosed by plain radiographs, the extent of the injury is often underappreciated. The advent of helical CT, especially with three-dimensional images of the skeletal system, has resulted in markedly improved diagnosis of sternal fractures. Although most nondisplaced sternal fractures are not associated with significant intrathoracic injuries, a conservative approach is to obtain a chest CT to rule out any other pathology. This may be clinically important in determining the best management of the sternal fracture in terms of conservative management versus surgical fixation. Chest CT also helps to rule out any associated mediastinal injuries.

Management

Treatment consists of providing adequate analgesia. In the absence of associated injuries, patients with isolated sternal fractures who can achieve adequate pain control with oral medications can be safely discharged home. However, a small subset of patients have sternal fractures that are displaced or produce overlying bone fragments that may cause severe pain, respiratory compromise, and, if untreated mechanically, result in nonunion. These patients are best referred for operative fixation.

COSTOCHONDRAL SEPARATION

Costochondral separation may also be caused by blunt anterior chest trauma. The signs and symptoms are similar to those of rib fracture, but because of the poor vascularity of healing cartilage, pain may persist for many weeks. The CXR film is usually normal, but there is a snapping sensation with deep respiration. Outpatient management of these patients is similar to that of patients with rib fractures. Flail chest can also occur from massive costochondral separation, but this is uncommon.

FLAIL CHEST

Epidemiology

Flail chest is a fairly uncommon injury and was found in almost one third of major trauma patients with chest injuries in a large series. Its exact incidence is unknown.

Anatomy/Pathophysiology

Flail chest results when three or more adjacent ribs are fractured at two points, allowing a freely moving segment of the chest wall to move in paradoxical motion (Fig. 42-2). Because of its common association with pulmonary contusion, it is one of the most serious chest wall injuries (Fig. 42-3).

Figure 42-2. Flail chest. Fracture of several adjacent ribs in two places with lateral flail or central flail segments.
The physiology of respiration is adversely affected by flail chest in a number of ways. The paradoxical motion of the chest wall is the hallmark of this condition, with the flail segment moving inward with inspiration and outward with expiration. Underlying pulmonary contusion is considered to be the major cause of respiratory insufficiency with flail chest. In addition, the pain of the injury causes muscular splinting with resultant atelectasis, hypoxemia, and decreased cardiac output.

**Clinical Features**

Flail chest is usually diagnosed by physical examination. This requires exposure of the patient’s thorax and examination of the chest wall for paradoxical motion. Pain, tenderness, and crepitus can direct the examiner. In addition, the flail segment can sometimes be visualized to move separately and in an opposite direction from the rest of the thoracic cage during the respiratory cycle. Endotracheal intubation and positive pressure ventilation will internally splint the chest wall, making the flail segment difficult to detect on physical examination.

**Diagnostic Strategies**

Multiple rib fractures can usually be identified on CXR films. CT scan is much more accurate than plain films in detecting the presence and extent of underlying injury and contusion to the lung parenchyma. It is utilized routinely in some centers for all patients with major chest trauma.

**Management**

Out-of-hospital or emergency department (ED) stabilization of the flail segment by positioning the person with the injured side down or placing a sandbag on the affected segments has been abandoned. These interventions actually inhibit expansion of the chest and increase atelectasis of the injured lung. Oxygen should be administered, cardiac and oximetry monitoring of the chest and increase atelectasis of the injured lung. Oxygen should be administered, cardiac and oximetry monitoring of the chest and increase atelectasis of the injured lung. Oxygen should be administered, cardiac and oximetry monitoring of the chest and increase atelectasis of the injured lung. Oxygen should be administered, cardiac and oximetry monitoring of the chest and increase atelectasis of the injured lung. Oxygen should be administered, cardiac and oximetry monitoring of the chest and increase atlecta

**Nonpenetrating Ballistic Injury**

**Epidemiology**

Many law enforcement officers, emergency medical services personnel, and private security guards wear lightweight synthetic body armor for protection against gunshot injury. In addition, there have been a number of reports of armed robbers wearing such vests in anticipation of exchanging gunfire with police or security personnel. These vests are “bullet resistant” rather than “bulletproof,” depending on the weapon being used against them. They are composed of many different combinations of synthetic fibers such as Kevlar.

Another type of nonpenetrating ballistic injury is caused by rubber bullets and beanbag shotgun shells. Rubber bullets have been used for many years by police agencies throughout
the world for crowd dispersal and for nonlethal use of force. Beanbag shotgun shells are nylon bags filled with pellets, which are fired from a standard shotgun. Both of these projectiles have the potential to cause serious injury despite their classification of “nonmetal” or “less than lethal” use of force.\(^1^9\)

**Anatomy/Pathophysiology**

Although bullet penetration is usually prevented, the heart, liver, spleen, lung, and spinal cord are vulnerable to nonpenetrating ballistic injury that may occur despite innocent-appearing skin lesions.

Bullet-resistant vests are usually capable of stopping penetration by the low-velocity missiles of most handguns, but the kinetic energy of the missile can be transmitted through the layers of protective cloth or armor and produce significant injury without penetration.

**Clinical Features**

Patients who have been shot with “less-than lethal projectiles” or with standard bullets while wearing bullet-resistant vests usually present with erythema, ecchymosis, and marked tenderness to palpation over the impacted area. There may be a projectile, such as a beanbag, still located in the wound. The area of tenderness and surrounding structures should be carefully palpated to identify any subcutaneous emphysema, crepitus, or bony step-offs.

**Diagnostic Strategies**

Plain film radiography should be used to identify any retained foreign bodies and any fractures or cortical violation. Strong consideration should be given for CT scanning based on the type of projectile, the clinical examination, and the degree of tenderness and location of the wounds.

**Management**

It is recommended that all victims of nonpenetrating ballistic injury be observed closely, with consideration for overnight observation. This is particularly true for injuries over the abdomen, where serial examinations in coordination with CT scanning will help to detect internal injuries that may present in a delayed manner. Use of protective body armor has resulted in significantly improved survival rates and has dramatically decreased the need for surgical intervention in those protected by it. In addition, “less than lethal” projectiles, such as rubber bullets and beanbag shotgun shells, offer law enforcement an alternative to conventional weapons that are considered “use of deadly force.” However, the possibility of an underlying injury resulting from this form of nonpenetrating ballistic injury should not be underestimated.

**TRAUMATIC ASPHYXIA**

**Anatomy/Pathophysiology**

Traumatic asphyxia is a rare syndrome caused by a severe compression of the thorax by a very heavy object causing a marked increase in thoracic and superior vena caval pressure, resulting in retrograde flow of blood from the right heart into the great veins of the head and neck. The vena cava and the large veins of the head and neck do not have valves and allow the transmission of pressure to the capillaries of the head and neck, which become engorged with blood.

**Clinical Features**

Traumatic asphyxia is characterized by a deep violet color of the skin of the head and neck, bilateral subconjunctival hemorrhages, petechiae, and facial edema. Stagnation develops from capillary atony and dilation, and as the blood desaturates, purplish discoloration of the skin occurs.\(^2^0\) Although the appearance of these patients can be quite dramatic, the condition is usually benign and self-limited.\(^2^0\)

**Diagnostic Strategies**

The clinical significance lies with the possibility of intrathoracic injury from the violent force necessary to produce traumatic asphyxia. Chest wall and pulmonary injuries are most common. If the patient’s examination and CXR show worrisome features, CT scanning of the chest should be performed.

Disturbance of vision has been attributed both to retinal hemorrhage, which is generally a permanent injury, and to retinal edema, which may cause transient changes in vision. One third of these patients lose consciousness, usually at the time of injury. Intracranial hemorrhages are rare, probably because of the shock-absorbing ability of the venous sinuses, but CT scan of the head should be done in patients with neurologic complaints. Neurologic manifestations typically clear within 24 to 48 hours, and long-term sequelae are uncommon.\(^2^1\)

**PULMONARY INJURIES**

**Subcutaneous Emphysema**

**Anatomy/Pathophysiology**

Subcutaneous emphysema in the presence of chest wall trauma usually indicates a more serious thoracic injury. Although the presence of air in the tissues is a benign condition, in cases of chest trauma it usually represents serious injury to any air-containing structure within the thorax. Air enters the tissues either extrapleurally or intrapleurally. Extrapleural tears in the tracheobronchial tree allow air to leak into the mediastinum and soft tissues of the anterior neck, producing a pneumomediastinum, which may progress to a tension pneumomediastinum. Intrapleural lesions, however, usually produce a pneumothorax by allowing air to escape the lung through the visceral pleura into the pleural space and then through the parietal pleura into the thoracic wall.

An esophageal tear resulting from Boerhaave’s syndrome or penetrating injury may also produce a pneumomediastinum manifested by subcutaneous emphysema over the supraclavicular area and anterior neck. An additional cause of subcutaneous emphysema, which may or may not be indicative of intrathoracic injury, is found immediately adjacent to a penetrating wound of the thorax. A small amount of air may be introduced into the adjacent subcutaneous tissues from the outside at the time of penetration. However, it must be assumed that this is secondary to a pneumothorax or pneumomediastinum, and appropriate diagnostic and therapeutic maneuvers to rule out or treat the intrathoracic injury should be carried out.

The presence of localized subcutaneous emphysema over the chest wall in the presence of blunt trauma is usually indicative of the presence of a traumatic pneumothorax, whereas the presence of subcutaneous emphysema over the supraclavicular area and anterior neck usually indicates a pneumomediastinum.
Rarely, a pneumomediastinum may progress to a tension pneumomediastinum, which may be life-threatening secondary to the presence of a tension pneumopericardium. This most often occurs in patients who are undergoing positive pressure ventilation and have a pneumopericardium visible on CXR examination. They may also have a Hamman’s crunch, which is a crunching sound with each heartbeat heard on cardiac auscultation.

Management

Tension pneumothorax must be considered and treated appropriately. If a tension pneumopericardium is suspected, then an immediate pericardiocentesis with aspiration of air from the pericardial space may be lifesaving.

Although subcutaneous emphysema is a benign condition, massive accumulations can be uncomfortable to the patient. The underlying cause, such as pneumothorax, ruptured bronchus, or ruptured esophagus, must be treated appropriately. Benign pneumomediastinum secondary to a Valsalva maneuver is treated with observation and high-flow oxygen to facilitate the reabsorption of nitrogen from tissues since the volume of nitrogen causes the discomfort.

Pulmonary Contusion

Epidemiology

Pulmonary contusion is reported to be present in 30 to 75% of patients with significant blunt chest trauma, most often from automobile collisions with rapid deceleration. Pulmonary contusion can also be caused by high-velocity missile wounds and the high-energy shock waves of an explosion in air or water. Pulmonary contusion is the most common significant chest injury in children, and it is most commonly caused by an automobile or pedestrian accident.

Anatomy/Pathophysiology

Pulmonary contusion is a direct bruise of the lung parenchyma followed by alveolar edema and hemorrhage but without an accompanying pulmonary laceration, as first described by Morgagni in 1761.

The early diagnosis of pulmonary contusion is important if treatment is to be successful. The onset may be insidious, and therefore it must be suspected from the history of the mechanism of injury rather than the initial CXR. Great force is required to produce pulmonary contusion, such as from a fall from height, motor vehicle crashes, and other forms of significant trauma.

Clinical Features

The clinical manifestations include dyspnea, tachypnea, cyanosis, tachycardia, hypotension, and chest wall bruising. There are no specific signs for pulmonary contusion, but hemoptysis may be seen sometime during the patient’s course, and moist rales or absent breath sounds may be heard on auscultation. Palpation of the chest wall commonly reveals fractured ribs. If a flail chest is discovered, pulmonary contusion is commonly present.

Surprisingly, many of the worst contusions occur in patients without rib fractures. It has been theorized that the more elastic chest wall, as in younger individuals, transmits increased force to the thoracic contents. Although isolated pulmonary contusions can exist, they are associated with extrathoracic injuries in the majority of patients.

Diagnostic Strategies

Care must be taken not to focus on more dramatic injuries at the expense of failing to recognize the evolving pulmonary contusion. This is particularly true with the initial x-ray studies when overlying rib fracture, pneumothorax, aspiration pneumonitis, or poor radiograph quality may mask the contusion.

Typical radiographic findings begin to appear within minutes of injury and range from patchy, irregular, alveolar infiltrate to frank consolidation (Fig. 42-4). Usually, these changes are present on the initial examination, and they are always present within 6 hours. The rapidity of changes on CXR visualization usually correlates with the severity of the contusion.

The increased frequency of CT scans for blunt trauma patients has resulted in a corresponding increase in the diagnosis of pulmonary contusions. CT scans have been shown to detect twice as many pulmonary contusions as plain radiographs. Some authors suggest that pulmonary contusions only visible on CT scan and not on plain radiographs may not be clinically significant.

Chest CT scan is particularly valuable to identify a pulmonary contusion in the acute phase after injury since plain CXRs have a low sensitivity. Although CT scan may not be necessary to make the diagnosis of a pulmonary contusion that is evident on plain chest radiography, it may be helpful to further define the extent of the contusion and to identify other thoracic injuries. Infectious complications, sternoclavicular joint dislocation, pneumothorax, misplaced endotracheal tube, intraperitoneal air, and vertebral fracture have all been identified by CT scan in the trauma patient.

Pulmonary contusion should be differentiated from the adult respiratory distress syndrome (ARDS) with which it is often confused because the radiographic appearance of the two conditions may be similar. The contusion usually manifests within minutes of the initial injury, is usually localized to a segment or a lobe, is often apparent on the initial chest study, and tends to last 48 to 72 hours. ARDS is diffuse, and its development is usually delayed, with onset typically between 24 and 72 hours after injury.

Arterial blood gases may be helpful in making the diagnosis of pulmonary contusion because most patients are hypoxemic at the time of admission. A low Po2 alone may be reason to suspect pulmonary contusion. A widening alveolar-arterial oxygen difference indicates a decreasing pulmonary diffusion capacity of the patient’s contused lung, and it is one of the earliest and most accurate means of assessing the current status, progress, and prognosis.
Management

Treatment for pulmonary contusion is essentially the same as that for flail chest. When only one lung has been severely contused and has caused significant hypoxemia, consideration should be given to intubating and ventilating each lung separately using a dual-lumen endotracheal tube and two ventilators. This allows for the difference in compliance between the injured and the normal lung and prevents hyperexpansion of one lung and gradual collapse of the other.26 As with flail chest, however, intubation and mechanical ventilation should be avoided if possible because they are associated with an increase in morbidity, including pneumonia, sepsis, pneumothorax, hypercoagulability, and longer hospitalization.

Certain patients may benefit from a trial of noninvasive positive pressure ventilation with CPAP in order to avoid intubation and mechanical ventilation. In those patients most severely injured with extensive pulmonary contusions and the development of ARDS with severe hypoxia refractory to conventional therapy, some small studies suggest a possible role for extracorporeal membrane oxygenation.27

Certain procedures may ameliorate the pulmonary contusion, including the restriction of intravenous fluids to maintain intravascular volume within strict limits and aggressive supportive care consisting of vigorous tracheobronchial toilet, suctioning, and pain relief. These maneuvers may preclude the need for ventilator support and allow a more selective approach to flail chest and pulmonary contusion.

Another area of controversy in the management of pulmonary contusions is the appropriate use of crystalloid versus colloid solutions in resuscitation of the multiply injured patient with suspected contusion. Because of the potential for colloid sequestration within the pulmonary alveoli due to capillary leak, colloids are not recommended for use in treating these patients.

Pneumonia is the most common complication of pulmonary contusions, and it significantly worsens the prognosis. It develops insidiously, especially in patients treated with prophylactic antibiotics. The use of antibiotics should be reserved for specific organisms rather than given prophylactically.

Pulmonary Laceration

The lungs are most often lacerated from penetrating injury, but they may also be injured by the inward projection of a fractured rib or avulsion of a pleural adhesion. These injuries are usually minor and rarely life-threatening, and they can usually be treated with observation or tube thoracostomy. Severe lacerations are present in only 3% of patients with thoracic trauma, and they are usually associated with hemopneumothorax, multiple displaced rib fractures, and hemothysis. Often, these life-threatening lacerations require thoracotomy with resection to control bleeding.

Pneumothorax

Epidemiology

Pneumothorax, which is the accumulation of air in the pleural space, is a common complication of chest trauma. It is reported to be present in 15 to 50% of patients, and it is invariably present in those with transpleural penetrating injuries.1

Anatomy/Pathophysiology

Pneumothorax can be divided into three classifications depending on whether air has direct access to the pleural cavity:

Figure 42-5. Closed pneumothorax. Simple pneumothorax is present in the right lung with air in the pleural cavity and collapse of the right lung.

- simple, communicating, and tension. A pneumothorax is considered simple (Fig. 42-5) when there is no communication with the atmosphere or any shift of the mediastinum or hemidiaphragm resulting from the accumulation of air. It can be graded according to the degree of collapse as visualized on the chest radiograph. A small pneumothorax occupies 15% or less of the pleural cavity, a moderate one 15 to 60%, and a large pneumothorax more than 60%. Traumatic pneumothorax is most often caused by a fractured rib that is driven inward, lacerating the pleura. It may also occur without a fracture when the impact is delivered at full inspiration with the glottis closed, leading to a tremendous increase in intra-alveolar pressure and the subsequent rupture of the alveoli. A penetrating injury such as a gunshot or stab wound may also produce a simple pneumothorax if there is no free communication with the atmosphere.

Communicating Pneumothorax. A communicating pneumothorax (Fig. 42-6) is associated with a defect in the chest wall and most commonly occurs in combat injuries. In the civilian sector, this injury is most commonly secondary to shotgun wounds. Air can sometimes be heard flowing sonorously in and out of the defect, prompting the term “sucking chest wound.” The loss of chest wall integrity causes the involved lung to paradoxically collapse on inspiration and expand slightly on expiration, forcing air in and out of the wound. This results in a large functional dead space for the normal lung and, together with the loss of ventilation of the involved lung, produces a severe ventilatory disturbance.

Tension Pneumothorax. The progressive accumulation of air under pressure within the pleural cavity, with shift of the mediastinum to the opposite hemithorax and compression of the contralateral lung and great vessels, is the constellation of findings in tension pneumothorax (Figs. 42-7 and 42-8). It occurs when the injury acts like a one-way valve, prevents free bilateral communication with the atmosphere, and leads to a progressive increase of intrapleural pressure. Air enters on inspiration but cannot exit with expiration. The resulting shift of mediastinal contents compresses the vena cava and distorts the cavoatrial junction, leading to decreased diastolic filling of the heart and subsequent decreased cardiac output. These changes result in the rapid onset of hypoxia, acidosis, and shock.

Clinical Features

Shortness of breath and chest pain are the most common presenting complaints of pneumothorax. The patient’s appearance is highly variable, ranging from acutely ill with cyanosis and tachypnea to misleadingly healthy. The signs and symp-

Trauma

Section Two

System Injuries

Figure 42-6. Communicating pneumothorax. Collapse of the right lung and air in the pleural cavity are seen, with communication to outside through a defect in the chest wall. In a sucking chest wound, lung volume is greater with expiration.

Figure 42-7. Tension pneumothorax seen in intubated patient.

Figure 42-8. Resolution of the tension pneumothorax seen in Figure 42-7 with placement of a left-sided tube thoracostomy.

A pneumothorax that is absent on initial CXR but is identified on subsequent chest or abdominal CT scan is called an occult PTX. Studies have found high rates of occult PTX diagnosed on abdominal CT that were absent on initial CXR (Fig. 42-9). One such study noted that two thirds of patients with occult PTX subsequently required tube thoracostomy.

The diagnosis and treatment of tension pneumothorax should not be delayed just because the patient is normotensive. Although tension pneumothorax usually occurs dramati-
cally, the clinical diagnosis is sometimes obscure, and CXR examination may be required to suggest the diagnosis. This film will show complete lung collapse and shift of the mediastinum to the opposite side. Ideally, the diagnosis and treatment should be completed without a CXR examination because the delay in obtaining this radiograph may adversely affect patient outcome.

Management

In the setting of penetrating trauma where the patient is asymptomatic and the initial CXR study is negative, the patient can be safely observed and the x-ray repeated. Previously, it was thought that if the patient was still asymptomatic and the radiograph negative after 6 hours, the patient could be discharged. Recent experience indicates that 3 hours is probably effective and safe for observation with repeat x-ray film before discharge for patients with penetrating trauma. Patients with blunt trauma with a high clinical suspicion for pneumothorax should still await a 6-hour delayed CXR prior to discharge. However, if the stable patient receives an initial screening chest CT that is negative for pneumo- or hemothorax, the literature suggests that obtaining a delayed CXR is unnecessary, and these patients may be discharged from the ED.

Simple Pneumothorax. Treatment of a simple pneumothorax depends on its cause and size. Most advocate treating a traumatic pneumothorax with a chest tube to correct any respiratory compromise; treatment with a chest tube is generally thought to be safer than observation in these patients. Small pneumothoraces, whether spontaneous or traumatic, have been treated with hospitalization and careful observation if the patient is otherwise healthy, symptom free, does not need anesthesia or positive pressure ventilation, and the pneumothorax is not increasing in size.

Isolated apical pneumothoraces of less than 25% may be observed in patients with stab wounds. This conservative method seldom has application in multisystem trauma, and a chest tube should be inserted immediately for any signs of deterioration. Some suggest that because it is small and lacks symptoms, occult traumatic pneumothorax found only on CT scan can be observed and does not need treatment. Studies indicate that these injuries can be handled like small but initially detectable pneumothoraces with observation in hemodynamically stable patients without symptoms. However, one third of those who require positive-pressure ventilation will have progression of the pneumothorax and will require tube thoracostomy, perhaps under exigent circumstances.

Any moderate to large pneumothorax should be treated with a chest tube. The indications for tube thoracostomy are listed in Box 42-1. The preferred site for insertion is the fourth or fifth intercostal space at the anterior or midaxillary line. If the tube is positioned posteriorly and directed toward the apex, it can effectively remove both air and fluid. This lateral placement of the tube is preferred not only because it is more efficient but also because it does not produce an easily visible cosmetic defect, as does the anterior site at the second interspace at the midclavicular line. With multisystem trauma, an adequate size chest tube (36–40 F in adults and 16–32 F in children) should always be used, particularly in cases of major trauma, when hemothorax is likely to occur.

Care must be taken to be certain the vent holes along the side of the tube are all inside the chest cavity. A radiopaque line along the side of the tube with interruptions at these drainage holes helps greatly when radiographically interpreting tube position. The tube should be attached to a water seal drainage system that allows reexpansion of the pneumothorax. If there is significant air leak or a large hemothorax, the tube may be connected to a source of constant vacuum at 20 to 30 cm H2O for more rapid reexpansion. Tube thoracostomy does have some potentially serious complications, including the formation of a hemothorax, pulmonary edema, broncho-pleural fistula, pleural leaks, empyema, subcutaneous emphysema, infection, and contralateral pneumothorax. To reduce the incidence of empyema and pneumonitis, current recommendations include the administration of empirical antibiotics with all tube thoracostomy placements. Pneumothoraces that have been present for more than 3 days should be reexpanded gradually without suction to avoid inducing reexpansion pulmonary edema.

Communicating Pneumothorax. For a patient with a communicating pneumothorax in the out-of-hospital setting, the defect should be covered immediately, which helps convert the condition to a closed pneumothorax and eliminates the major physiologic abnormality. An occlusive dressing of petrolatum gauze can be applied, but care should be taken because this can convert the injury to a tension pneumothorax, especially in patients who are intubated and undergoing positive-pressure ventilation. The wound should never be packed because the negative pressure during inspiration can suck the dressing into the chest cavity. These considerations are not as important once the patient is in the ED, where endotracheal intubation and tube thoracostomy can be performed. Positive-pressure ventilation can then be started without the fear of

---

**Figure 42-9.** Occult pneumothorax. Large left-sided pneumothorax seen on chest CT scan, which was not visible on chest x-ray.

**BOX 42-1 INDICATIONS FOR TUBE THORACOSTOMY**

- Traumatic cause of pneumothorax (except asymptomatic, apical pneumothorax)
- Moderate to large pneumothorax
- Respiratory symptoms regardless of size of pneumothorax
- Increasing size of pneumothorax after initial conservative therapy
- Recurrence of pneumothorax after removal of the initial chest tube
- Patient requires ventilator support
- Patient requires general anesthesia
- Associated hemothorax
- Bilateral pneumothorax regardless of size
- Tension pneumothorax

producing a tension pneumothorax, and the patient can be prepared for definitive surgical repair.

**Tension Pneumothorax.** When the diagnosis of tension pneumothorax is suspected clinically, the pressure should be relieved immediately with needle thoracostomy, which is performed by inserting a large-bore (14-gauge or larger) catheter, at least 5 cm in length, through the second or third interspace anteriorly or the fourth or fifth interspace laterally on the involved side. This method can be easily performed in the field or ED, allowing vital signs to improve during transport or preparation for a tube thoracostomy.  

The intubated patient in the ED who is receiving positive-pressure ventilation and external cardiac compressions is at particular risk for developing tension pneumothorax. Fractured ribs from cardiopulmonary resuscitation (CPR) can penetrate lung parenchyma and cause pneumothorax. Positive-pressure ventilation then increases intrapleural pressure and produces a tension pneumothorax. The earliest sign of this complication is an increase in resistance to ventilation. If the patient has vital signs, the blood pressure will fall and the central venous pressure (CVP) will rise. Misplacement of an endotracheal tube does not result in tension pneumothorax but, rather, asymmetry of breath sounds. If tension pneumothorax is suggested, the clinician should proceed with therapy.

**Hemothorax**

**Epidemiology**

Hemothorax, which is the accumulation of blood in the pleural space after blunt or penetrating chest trauma, is a common complication that may produce hypovolemic shock and dangerously reduce vital capacity. It is commonly associated with pneumothorax (25% of cases) as well as extrathoracic injuries (73% of cases).  

**Anatomy/Pathophysiology**

Hemorrhage from injured lung parenchyma is the most common cause of hemothorax, but this tends to be self-limited unless there is a major laceration. Specific vessels are less often the source of hemorrhage, with intercostal and internal mammary arteries causing hemothorax more often than hilar or great vessels. Bleeding from the intercostal arteries may be brisk, however, because they branch directly from the aorta.

**Management**

Close monitoring of the initial and ongoing rate of blood loss must be performed. Immediate drainage of more than 1500 mL of blood from the pleural cavity is usually considered an indication for urgent thoracotomy. Perhaps even more predictive of the need for thoracotomy is a continued output of at least 200 mL/hr for 3 hours. General considerations for urgent thoracotomy are outlined in Box 42-2.  

**Clinical Features**

Depending on the rate and quantity of hemorrhage, varying degrees of hypovolemic shock will be manifested. Tactile fremitus is decreased, and breath sounds are diminished or absent.

**Diagnostic Strategies**

Blunting of the costophrenic angles on upright chest radiograph requires at least 200 to 300 mL of fluid. The supine view chest film is less accurate, and it may be more difficult to make the diagnosis with the patient in this position. Unfortunately, this is often the only film available because of the patient’s unstable condition. In the supine patient, blood layers posteriorly, creating a diffuse haziness that can be rather subtle, depending on the volume of the hemothorax (Fig. 42-10).

As is the case with pneumothoraces, CT scan has much greater sensitivity than chest radiography in the detection of hemothorax, with some studies reporting up to a 25% incidence of hemothoraces diagnosed by CT that were not detected on chest radiography. Perhaps more important, almost half of these occult hemothoraces underwent drainage with tube thoracostomy (Fig. 42-11). Delayed hemothorax may be associated with significant morbidity because the residual blood may serve as a nidus for the development of empyema or fibrothorax.

**Figure 42-10.** Hemothorax secondary to gunshot wound. Note haziness over right hemithorax with bullet seen in right upper lobe.

---

**BOX 42-2 INDICATIONS FOR THORACOTOMY**

- Initial thoracostomy tube drainage is >20 mL/kg of blood
- Persistent bleeding at a rate >7 mL/kg/hr
- Increasing hemothorax seen on chest x-rays
- Patient remains hypotensive despite adequate blood replacement, and other sites of blood loss have been ruled out
- Patient decompensates after initial response to resuscitation
Autotransfusion has been successfully used in tube thoracostomy. Recent simplification and commercial availability of the equipment have made autotransfusion feasible in most EDs. Autotransfusion also eliminates the risk of incompatibility reactions and transmission of certain diseases such as hepatitis C. Because the majority of blood loss occurs immediately after tube thoracostomy placement, autotransfusion apparatus must be immediately available in the ED.

As a result of the increasing frequency of chest CT scans, it has been found that there may be a greater frequency of misplaced thoracostomy tubes than is evident on conventional chest radiographs. Almost 25% of patients in one series subsequently required operative intervention as a result of complications from penetration of the lung parenchyma from tube thoracostomies.41 (Fig. 42-12)

Although beyond the scope of emergency medicine, mention is made of the role of thoracoscopy. Video-assisted thoracic surgery (VATS) is particularly useful for evaluation and evacuation of retained hemothorax, control of bleeding from intercostal vessels, and diagnosis and repair of diaphragmatic injuries.42 As surgeons gain more experience with the technique, VATS will likely become more widely used for other indications as well, given the decreased morbidity and length of hospital stay compared to open thoracotomy.43

# TRACHEOBRONCHIAL INJURY

## Epidemiology

Tracheobronchial injuries may occur with either blunt or penetrating injuries of the neck or chest. Penetrating injuries tend to be more obvious because of their nature, alerting both the patient and the physician, whereas blunt injuries can be occult. Motor vehicle collisions are the most frequent mechanism causing tracheobronchial injury, accounting for more than half of all cases.44

Although there has been an increase in the occurrence of tracheobronchial disruption, it is still a relatively rare injury, occurring in fewer than 3% of patients with significant chest injury. Its associated mortality rate is reported to be approximately 10%, although mortality rates are significantly affected by associated injuries and the timing of diagnosis and surgical repair.45,46

## Anatomy/Pathophysiology

Tracheobronchial injuries caused by knife wounds develop almost exclusively from wounds in the cervical trachea, whereas gunshot wounds may damage the tracheobronchial tree at any point. Intrathoracic injury to the tracheobronchial tree occurs most commonly from blunt trauma. These injuries may result from direct blows, shearing stresses, or burst injury. A direct blow to the neck may crush the cervical tracheal against the vertebral bodies and transect the tracheal rings or cricoid cartilage. Shear forces on the trachea will produce injury at the carina and the cricoid cartilage, which are its relatively fixed points.

Sudden deceleration of the thoracic cage, as occurs in a decelerating auto accident, pulls the lungs away from the mediastinum, producing traction on the trachea at the carina. When the elasticity of the tracheobronchial tree is exceeded, it ruptures. It has also been suggested that if the glottis is closed at the time of impact, the sudden increase in intrabronchial pressure will rupture the tracheobronchial tree. Regardless of the mechanism, more than 80% of these injuries occur within 2 cm of the carina.

## Clinical Features

Massive air leak, hemoptysis, and subcutaneous emphysema should suggest the diagnosis of major airway damage. Subcutaneous emphysema is typically the most common physical finding.46 Auscultation of the heart may reveal a Hamman’s crunch. Patients with tracheobronchial disruption have one of two distinct clinical pictures. In the first group of patients, the wound opens into the pleural space, producing a large pneumothorax. A chest tube fails to evacuate the space and reexpand the lung, and there is continuous bubbling of air in the underwater seal device.

In the second group of patients, there is complete transection of the tracheobronchial tree but little or no communication with the pleural space. A pneumothorax is not usually present. The peribronchial tissues support the airway enough to maintain respiration, but within 3 weeks granulation tissue will obstruct the lumen and produce atelectasis. These patients are relatively free of symptoms at the time of injury but weeks later have unexplained atelectasis or pneumonia. Radiographic signs in either group of patients are pneumomediastinum, extensive subcutaneous emphysema (Fig. 42-13), pneumothorax, fracture of the upper ribs (first through fifth), air surrounding the bronchus, and obstruction in the course of an air-filled bronchus.
Diagnostic Strategies

When tracheobronchial injury is suspected, bronchoscopy should be performed. Fiberoptic bronchoscopy is the most reliable means of establishing the diagnosis and determining the site and extent of the injury. However, CT scan has been shown to have high sensitivity in detecting tracheobronchial injury.47 Bronchopleural fistula (a communication between a bronchus and the lung parenchyma) can occur as a complication of tracheobronchial disruption and in some cases has been treated successfully via the fiberoptic bronchoscope. A mediastinal fluid collection and/or evidence of mediastinitis may be noted on chest CT.

Management

If possible, endotracheal intubation over a bronchoscope should be performed since it allows visualization of the tube as it passes beyond the site of injury. When attempting blind intubation, care must be taken to not place the endotracheal tube through a transected airway into the soft tissue or a false passage or to convert a partial tracheal tear into a complete one.

The standard treatment for tracheobronchial injury has been surgery. However, conservative medical treatment of such injuries has been reported for tracheobronchial injury patients who meet strict selection criteria. These include patients without any major symptoms, including esophageal-associated injuries, progressive subcutaneous or mediastinal emphysema, severe dyspnea requiring intubation, difficulty with mechanical ventilation, pneumothorax with an air leak through the chest drains, open tracheal injuries, or mediastinitis.46 In most cases, thoracotomy with intraoperative tracheostomy and surgical repair of the disrupted airway should be performed as soon as possible.

DIAPHRAGMATIC INJURY

Epidemiology

Diaphragmatic rupture is present in 1 to 6% of major thoracic injuries.45,46 Diaphragmatic rupture occurs most commonly after blunt thoracoabdominal trauma, such as occurs in motor vehicle accidents or falls from heights.

Anatomy/Pathophysiology

Diaphragmatic hernia is a herniation of abdominal structures within the thoracic cavity through a defect on the diaphragm. Because of pressure gradients across the diaphragm, these injuries are associated with herniation and a potential risk of strangulation of abdominal viscera. Signs and symptoms may not occur during trauma center admission and may be delayed for as long as months to years.49 In one study, delayed recognition of incarcerated diaphragmatic hernia after stab wounds to the lower chest and upper abdomen was associated with a mortality rate of 36%.50

When diaphragmatic rupture secondary to blunt trauma occurs, the right hemidiaphragm is ruptured in 15 to 24% of cases and the left in 70 to 80%. Five to 8% of cases are bilateral. It is generally accepted that this is due to the protective effect of the liver on the right hemidiaphragm. In penetrating injuries of the upper abdomen and lower thorax, such as from gunshot wounds and stab wounds, possible diaphragmatic injury should be considered.

In cases of blunt injury, the raised pressure within the abdominal cavity causes the tear of the diaphragm, and the pressure difference forces the abdominal organs through the diaphragmatic defect. Because blunt trauma can cause multiple organ injuries, these coexisting injuries can mask the more silent diaphragmatic injuries and diaphragmatic rupture may be initially overlooked. Negative intrathoracic pressure generated by inspiration tends to draw abdominal contents into the thorax. This effect is lost with the use of intubation and positive-pressure ventilation. Because there is also a plugging effect of the viscera over the defect, migration of the abdominal organs within the thorax is usually delayed, so these injuries are diagnosed in only 10% of cases in the acute phase.51 An overlooked diaphragmatic injury in the acute phase sometimes presents as a hernia with obstruction, incarceration, or perforation of bowel many years later.

Diagnostic Strategies

The diagnosis and management of diaphragmatic injuries are problematic because these injuries present with variable clinical and radiological signs. Accurate diagnosis of traumatic diaphragmatic hernia is essential because prompt surgical repair is the treatment of choice.

Chest radiography is the first imaging study to determine the presence of diaphragmatic rupture, but a plain chest radiograph immediately after the accident presents suspicion about the diagnosis of a ruptured diaphragm in only 20 to 34% of cases. CT examination of the abdomen and chest is a very useful and reliable tool in the evaluation of blunt diaphragmatic injury, but the injury site and type affect its sensitivity.52 CT can demonstrate findings consistent with diaphragmatic injury, such as diaphragmatic discontinuity, intrathoracic herniation of abdominal contents, and waistlike constriction of abdominal viscera (the “collar sign”). An isolated omental herniation is clearly detected on nonenhanced CT due to its fatty nature and crescent shape, and a CT with intravenous contrast will more clearly reveal the contrast-enhancing omental vessels. If the stomach or intestine is herniated, distended intestinal segments containing air-fluid levels are visualized on the supine position images. It is reported that helical CT can be used to detect 78% of left-sided and 50% of right-sided injuries.53 Efflux of peritoneal lavage fluid through a thoracostomy tube is also diagnostic of a diaphragmatic hernia.

Although magnetic resonance imaging is not useful in most traumatic diaphragmatic hernia cases due to its relatively long duration and sensitivity for motion artifact, it is preferred in
selected patients, especially in delayed traumatic diaphragmatic herniation cases from small penetrating injuries. Laparoscopy for diagnosis and repair of small left-sided diaphragmatic injury due to penetrating trauma is the preferred modality.54 Patients with right-sided small penetrating lesions typically do not experience herniation because of the protective effect of the dome of the liver on the right side.

Management

Because diaphragmatic injuries have been taken as a predictor of serious associated injuries in trauma and a marker of severity,55 prompt treatment of diaphragmatic rupture is important in the trauma patient. The treatment of choice is surgery. CT scan should identify the site and extent of herniation, herniated organs, complications, and damage to associated organs. Although they are not without complications, laparoscopy and thoracoscopy may be used for diaphragmatic hernia repair.

The incidence of diaphragmatic involvement after penetrating thoracoabdominal injury is high, making nonoperative, expectant management of these patients potentially unsafe. Mandatory evaluation of the diaphragm with laparoscopy to exclude injury in all asymptomatic, hemodynamically normal patients is recommended.55 In the absence of significant hemoperitoneum or other factors preventing adequate visualization of the diaphragm, laparoscopy is a sensitive means of excluding occult diaphragmatic injury in these patients. When significant hemoperitoneum is encountered on laparoscopy or other factors are present that prohibit adequate evaluation of the diaphragm, conversion to an open exploration should be considered to fully visualize the diaphragm at risk and exclude additional injuries.

CARDIOVASCULAR TRAUMA

Blunt Cardiac Trauma

Epidemiology

Blunt cardiac injury usually results from high-speed motor vehicle collisions, in which the chest wall strikes against the steering wheel. Other causes, such as falls from heights, crushing injuries, blast injuries, and direct blows, are less common. The significance of blunt injuries as a cause of myocardial or cardiac contusion was described more than 50 years ago by Bright and Beck.56 Nevertheless, the diagnosis of a blunt injury to the heart remains elusive because of the usual concomitant serious injuries to other body organs and, more important, because there is no gold standard for making the diagnosis.

The importance of detecting blunt myocardial injury lies in the recognition of associated potentially fatal complications. Life-threatening dysrhythmias, conduction abnormalities, congestive heart failure, cardiogenic shock, hemopericardium with tamponade, cardiac rupture, valvular rupture, intraventricular thrombi, thromboembolic phenomena, coronary artery occlusion, ventricular aneurysms, and constrictive pericarditis have all been reported as complications.

Anatomy/Pathophysiology

Blunt cardiac trauma may be viewed as part of a continuous spectrum (i.e., myocardial concussion, contusion, infarction, and rupture).57 Myocardial concussion occurs when a blunt injury to the interior chest produces a “stun” response in the myocardium. No permanent cellular injury occurs, but transient clinical effects may result. Myocardial contusion is the least severe form of injury that can be demonstrated pathologically. Cellular injury occurs with extravasation of red blood cells into the muscle wall, along with localized myocardial cellular necrosis. Permanent myocardial damage is rare. Traumatic myocardial infarction (MI) results from either direct trauma to the coronary arteries or a severe contusion of the myocardium, leading to irreversible cellular injury and ultimately cell death. Direct injury to the coronary arteries via laceration, thrombosis, or spasm is thought to be the most common mechanism for traumatic MI. Cardiac rupture is obviously the most severe form of blunt cardiac injury.

Myocardial Concussion

The term myocardial concussion or commotio cordis is used to describe an acute form of blunt cardiac trauma that is usually produced by a sharp, direct blow to the midanterior chest that stuns the myocardium and results in brief dysrhythmia, hypotension, and loss of consciousness. If the patient survives the initial dysrhythmia, there are no lasting histopathologic changes, and it is difficult to make the definitive diagnosis of myocardial concussion. This presumptively explains those cases of sudden death after a blow to the chest in which no histopathologic changes in the myocardium are demonstrated at autopsy.58

If prolonged cellular dysfunction occurs, it may result in a nonperfusing rhythm, such as asystole or ventricular fibrillation, and irreversible cardiac arrest. There are a number of documented cases of successful resuscitation with rapid provision of CPR and the use of an automated external defibrillator.59

Myocardial Contusion

Epidemiology

Myocardial contusion has been a diagnosis describing a very poorly understood and nebulous condition. Decades of research and widely varied clinical practice have failed to produce a consensus regarding its diagnosis, complication rate, and proper disposition. The incidence of myocardial contusion varies from 3 to 55% in reported series of severe closed-chest trauma, depending on the criteria used for establishing the diagnosis.60,61

Anatomy/Pathophysiology

Several mechanisms have been postulated by which the heart may be injured in cases of nonpenetrating trauma. A direct blow to the chest transmits energy through the ribs to the spine. When a large force is applied to the chest wall over an extended period, the sternum is displaced posteriorly, and the heart is compressed between the sternum and vertebrae or an elevated diaphragm. Either can result in cardiac injury. Increased intrathoracic pressure from a direct blow to the chest may contribute to the injury. In addition, compression of the abdomen and pelvis may displace abdominal viscera upward and result in cardiac injury.

A myocardial contusion is histologically characterized by intramyocardial hemorrhage, edema, and necrosis of myocardial muscle cells. These histologic findings are similar to those seen in acute MI. An accumulation of edema and cellular infiltrate in the wall of the heart may result in a decrease in ventricular compliance, resulting in cardiac dysfunction.

Most myocardial contusions heal spontaneously, with resolution of cellular infiltrate and hemorrhage leading to scar for-
mation. Small pericardial effusions occur in more than 50% of cases of contusion, usually during the second week. These are probably caused by pericardial irritation, and they neither imply significant cardiac injury nor increase the risk of tamponade. A fibrinous reaction at the contusion site may also occur, resulting in pain, a friction rub, and adhesion to the pericardium. In a few cases, the reabsorption of the hematoma is accompanied by necrosis of the ventricular wall, which may result in a delayed rupture of the myocardium or a scarred and weakened area with subsequent development of a ventricular aneurysm. If necrosis occurs, it will usually be manifested in the second week after injury and is one of the causes of delayed sudden death after blunt trauma to the chest.

Clinical Features

Myocardial contusion presents clinically as a spectrum of injuries of varying severity. Although the majority of patients with myocardial contusion have external signs of thoracic trauma (e.g., contusions, abrasions, palpable crepitus, rib fractures, or visible flail segments), the absence of thoracic lesions decreases the suspicion but never excludes cardiac injury. Other associated injuries may include pulmonary contusion, pneumothorax, hemothorax, external fracture, and great vessel injury. The most sensitive but least specific sign of myocardial contusion is sinus tachycardia, which is present in approximately 70% of patients with documented myocardial contusions. A reduction in cardiac output, which can be clinically insignificant or manifest as pronounced cardiogenic shock, may occur in patients with significant cardiac contusion.

Diagnostic Strategies

Significant controversy exists regarding the importance of establishing the diagnosis of myocardial contusion in otherwise hemodynamically stable patients.62

Even when the diagnosis of a myocardial contusion is considered, confirming the diagnosis without a true gold standard is problematic. Clinical evidence is often nonspecific, especially in the setting of multiple trauma. Patients may have dysrhythmias or ST wave changes caused by significant hypoxia as a result of pulmonary injuries or blood loss, which are reversed once the hypoxemia or blood loss is corrected. Likewise, severe intracranial injury, electrolyte abnormalities, and excessive vagal or sympathetic tone may give rise to dysrhythmias or an abnormal electrocardiogram (ECG). Under these conditions, ECG abnormalities may not represent true myocardial damage. On the contrary, they may cause one to overlook the potential for traumatic cardiac injury. One large series of blunt trauma patients found that blunt cardiac injury was a significant risk factor for cardiac dysrhythmia.63

Because myocardial contusion cannot be positively identified short of biopsy or autopsy, there is much confusion regarding the role of the various laboratory and imaging studies used to diagnose myocardial injury. Multiple studies utilizing cardiac biomarkers have been unhelpful in establishing or excluding the diagnosis. Furthermore, the vast majority of myocardial contusions probably do not cause clinically significant complications. Based on mechanism alone, the relative risk of a life-threatening dysrhythmia is far too low to warrant routine admission to rule out myocardial contusion in all patients with blunt chest trauma. Several studies suggest that very few patients diagnosed with myocardial contusion develop cardiac complications requiring therapeutic intervention or a change in management. Therefore, a routine cardiac workup is not indicated in most blunt thoracic trauma victims.62 The usefulness of diagnostic studies is to identify patients at low risk who can be safely discharged from the ED and not to diagnose the presence of a myocardial contusion.

Diagnostic strategies that have been used to “diagnose” myocardial contusion and assess the risk of complications and the need for admission include ECG, biochemical cardiac markers (serum creatinine kinase [CK-MB] isoenzyme levels or troponin I or T levels), two-dimensional echocardiography, and CT scan.

**Electrocardiogram.** The ECG after blunt chest trauma may be normal or may show nonspecific abnormalities. Because of its anterior position in the thorax and proximity to the sternum, the right ventricle is far more likely to be injured than the left ventricle. The standard 12-lead ECG is relatively insensitive to right ventricular damage, as demonstrated by pathologic evidence of cellular damage in patients with normal ECGs. A cardiac contusion usually results in moderate right ventricular damage with only minor electrical changes, which can easily be missed on ECG. Right-sided ECGs (the addition of V4R) have not been found to be of any benefit.64

Little is known about the relative risk of dysrhythmia as a function of the ECG abnormality, and any new ECG finding warrants consideration of further diagnostic studies or admission for further monitoring. A severely injured right ventricle may cause a right bundle branch block, usually transient. Less commonly, various degrees of atioventricular block have been documented after blunt chest trauma. Sinus tachycardia and ventricular and atrial extrasystoles are the most frequently reported rhythm disorders. More serious arrhythmias, such as atrial fibrillation, ventricular tachycardia, and ventricular fibrillation, occur less often but may acutely compromise the hemodynamic state or even result in sudden death.63

A few cases of delayed life-threatening dysrhythmia have been reported up to 12 hours after injury, and patients may develop less lethal dysrhythmias up to 72 hours after injury. The onset of ECG changes may be delayed up to 48 hours after injury, and all ECG changes usually resolve in 4 to 60 days.65 The presence of ECG abnormalities is neither specific enough to confirm the diagnosis of myocardial contusion nor reliable enough to predict subsequent complications.

**Cardiac Enzymes.** Since myocardial contusion is histologically characterized by intramyocardial hemorrhage and necrosis of myocardial muscle cells, similar to those seen in acute myocardial infarction, cardiac enzymes were the first screening tool used to detect myocardial injury. Creatine kinase is nonspecifically increased in trauma patients due to associated skeletal muscle injury, and CK-MB levels have also been found to be falsely elevated and thus be very nonspecific in multitrauma patients. Thus, the use of CK-MB levels is of very limited utility to screen for myocardial contusion and is no longer recommended.65,67

Although serum cardiac troponin is highly specific for myocardial injury in the setting of acute myocardial infarction, elevated troponin levels have been found to have much lower sensitivity for myocardial contusion, and they may occur in the absence of a significant direct myocardial contusion.65 However, such studies are limited because no true gold standard exists to confirm the diagnosis. Several studies have suggested that the combination of a normal troponin and a normal 12-lead ECG has a negative predictive value to “rule out” myocardial contusion of 100%, suggesting that these patients do not need any other workup or monitoring specific to possible myocardial contusion.65 If there is concern due to nonspecific ECG abnormalities or an elevated troponin level on initial evaluation in the ED, a secondary measurement after 4 to 6 hours should be performed to reliably exclude myocardial injury.65,66

**Echocardiography.** Echocardiography provides a means for direct visualization of cardiac structures and chambers. Since
contused myocardium resembles infarcted myocardial tissue both histologically and functionally, two-dimensional echocardiography is useful in diagnosing myocardial contusion by evaluating wall motion abnormalities. It is also useful in identifying associated lesions such as thrombi, pericardial effusion, and valvular disruption. Furthermore, echocardiography offers the practical advantages of being portable, noninvasive, and easy to use at the bedside. If patients have painful chest wall injuries, transthoracic echocardiography may be limited. In these cases, transesophageal echocardiography (TEE) is an alternative.61,62

Management

Appropriate workup and treatment of the patient with suspected myocardial contusion begins with accurate out-of-hospital evaluation. Paramedics should observe and relay information to the ED concerning mechanism of injury, status of the motor vehicle, steering wheel and dashboard damage, use of seat belts and air bags, speed of the vehicle before the accident, and position of the patient when found. Pertinent clinical data to be recorded include vital signs, level of consciousness, cardiac rhythm, and the presence of chest wall trauma.

The value of admitting and carefully monitoring patients with suspected mild cardiac contusions is not supported. The latest studies do suggest that troponin levels are very helpful in risk stratification of patients suspected of having myocardial contusion.65,66 One such strategy is to obtain an emergent echocardiography for all severely injured patients who present with hemodynamic instability and are suspected to have structural damage to the heart and/or great vessels. A similar recommendation exists for severely injured patients with a sternal fracture, although the presence of an isolated sternal fracture is not necessarily a sign of cardiac injury. Increased levels of troponin I or troponin T or ECG abnormalities indicate a higher risk of developing cardiac complications. Further investigation, including echocardiography, serial ECGs, and serial troponin levels, is recommended.61,66,68

In patients who have minor injuries and are otherwise asymptomatic, elevated levels of troponin I or T and minor ECG abnormalities do not necessarily indicate a clinically significant myocardial contusion. Very few of these patients will develop complications. However, normal troponin I or T levels (4–6 hours after injury) along with normal (or unchanged) ECGs correlate with minimal risk of cardiac complications. Therefore, in-hospital monitoring may be limited to those patients with significant, acute ECG abnormalities and/or elevated troponin concentrations. Serial ECGs and troponins should be obtained until the results return to normal.

Echocardiography is rarely required in this low-risk subset of patients who have minor injuries and are otherwise asymptomatic. If the patient’s clinical status deteriorates, or there is inconsistency between the troponins and ECG changes, echocardiography can be very useful to rule out structurally significant myocardial injuries.

On admission, treatment of a suspected myocardial contusion should be similar to that of an MI: intravenous line, cardiac monitoring, and administration of oxygen and analgesic agents. Dysrhythmias should be treated with appropriate medications as per current advanced cardiac life support guidelines.69 No data exist to support prophylactic pharmacologic agents for dysrhythmia suppression. Measures should be taken to treat and prevent any conditions that increase myocardial irritability (e.g., metabolic acidosis).64 Thrombolytic agents and aspirin are contraindicated in the setting of acute trauma. In rare instances of acute MI associated with trauma, angioplasty may be a treatment option.

In the setting of depressed cardiac output caused by myocardial contusion, judicious fluid administration is required. Dobutamine may be useful after optimal preload is ensured. Intra-aortic balloon counterpulsation has been used successfully in refractory cardiogenic shock. The priority is to be certain that the decreased cardiac output is not the result of other undiagnosed injuries, particularly aortic rupture.

Prognosis

The prognosis of a patient with myocardial contusion depends on the character and magnitude of the initial trauma, the size and location of the contusion, the preexisting condition of the coronary arteries, and, most important, any other organ trauma and its complications. Major morbidity and mortality correlate most closely with the number of associated serious injuries. Recovery without complications is the usual course.

Myocardial Rupture

Myocardial rupture refers to an acute traumatic perforation of the ventricles or atria, but it may also include a pericardial rupture or laceration or rupture of the interventricular septum, interatrial septum, chordae, papillary muscles, or valves. A delayed rupture of the heart may also occur weeks after nonpenetrating trauma, probably as a result of necrosis of a contused or infarcted area of myocardium.

Epidemiology

High-speed motor vehicle crashes are responsible for most cases of traumatic myocardial rupture. Myocardial rupture is almost always immediately fatal and accounts for 15% of fatal thoracic injuries. It has been estimated that blunt cardiac rupture accounts for 5% of the 50,000 annual highway deaths in the United States.1 In various series, the incidence of cardiac rupture in cases of blunt chest trauma ranges from 0.5 to 2%.71 The most common cause of death in cases of nonpenetrating cardiac injuries is myocardial rupture. Approximately one third of these patients have multiple chamber rupture and one fourth have an associated ascending aortic rupture. Bright and Beck reviewed 152 autopsy cases of traumatic cardiac ruptures and found that 20% of patients survived 30 minutes or more, which would have allowed them to reach the operating room had the problem been recognized.56 The first report of successful repair of blunt cardiac rupture was published in 1955 and involved a patient with right atrial rupture.70

Anatomy/Pathophysiology

The chambers most commonly involved in cardiac rupture are the ventricles; ruptures occur almost equally on each side. Ruptures of the atria are less common, with right atrium rupture being more common than left. Multiple chamber involvement occurs in 20% of patients.70 Twenty percent of nonsurvivors have concomitant aortic rupture.

A rupture occurs during closure of the outflow track when there is ventricular compression of blood-filled chambers by a pressure sufficient to rupture the chamber wall, septum, or valve. This is the most likely mechanism for ventricular rupture when injury occurs in diastole or early systole concomitant with maximal ventricular distension. The atria are most susceptible to rupture by sudden compression in late systole when these chambers are maximally distended with venous blood and the atrial ventricular valves are closed. Other
proposed mechanisms of rupture include (1) deceleration shearing stresses acting on the “fixed” attachment of the inferior and superior vena cava at the right atrium; (2) upward displacement of blood and abdominal viscera from blunt abdominal injury that causes a sudden increase in intracardiac pressure; (3) direct compression of the heart between the sternum and vertebral bodies; (4) laceration from a fractured rib or sternum; and (5) complications of a myocardial contusion, necrosis, and subsequent cardiac rupture.

Because of the nature of the mechanisms involved in cardiac rupture, associated multisystem injuries are common. More than 70% of reported survivors of myocardial rupture have other major associated injuries, including pulmonary contusions, liver and spleen lacerations, closed-head injuries, and major fractures. Twenty percent of nonsurvivors have concomitant aortic ruptures.72

The immediate ability of the patient to survive cardiac rupture depends on the integrity of the pericardium. Two thirds of patients with cardiac rupture have an intact pericardium and are protected from immediate exsanguination. These patients may survive for variable periods but eventually develop significant hemopericardium and pericardial tamponade. One third of patients with cardiac rupture have associated pericardial tears and succumb promptly to exsanguination.

Occasionally, patients survive if the pericardial tear is small or the rupture is small enough to seal itself. A small pericardial laceration may allow partial and intermittent release of tamponade while still controlling bleeding. In one series of patients with confirmed myocardial rupture, 40% of patients had isolated rupture of the right atrium. The overall mortality rate was 81%, with none of the patients with two chamber rupture, ventricular rupture, or absence of vital signs upon arrival at the ED surviving.70,72

Clinical Features

The clinical presentation of a patient who has sustained a myocardial rupture is usually that of cardiac tamponade or severe hemorrhage. Rarely, a patient is seen with a large hemothorax, hypotension, and hypovolemia, suggesting rupture with associated pericardial tear. A patient with an intact pericardial sac and developing tamponade displays physical findings of tamponade usually with subsequent clinical deterioration. Initial inspection of the torso may reveal little more than a bruised area over the sternum or no external physical evidence. More often, however, signs of significant chest trauma or other associated injuries will be present indicating a mechanism of injury that could result in myocardial rupture. Auscultation may reveal a harsh murmur, known as a “bruit de moulin,” which sounds like a splashing mill wheel.

In a review of survivors of myocardial rupture, common symptoms and signs included hypotension (100%); elevated CVP (95%); tachycardia (89%); distended neck veins (80%); cyanosis of the head, neck, arms, and upper chest (76%); unresponsiveness (74%); distant heart sounds (61%); and associated chest injuries (50%).70,72,73

The following findings are suggestive of pericardial rupture:

1. Hypotension disproportionate to the suspected injury
2. Hypotension unresponsive to rapid fluid resuscitation
3. Massive hemothorax unresponsive to thoracostomy and fluid resuscitation
4. Persistent metabolic acidosis
5. The presence of pericardial effusion on echocardiography or elevation of CVP and neck veins with continuing hypotension despite fluid resuscitation

Diagnostic Strategies

Early use of ED ultrasound may facilitate the early diagnosis of cardiac rupture and pericardial tamponade.74 The combination of shock and jugular venous distension (or an elevated CVP) in a patient with blunt chest trauma should immediately suggest pericardial tamponade. However, in patients withassociated hemorrhage from other injuries, JVD may be absent. Other considerations include tension pneumothorax, right ventricular myocardial contusion, superior vena cava obstruction, ruptured tricuspid valve, or preexisting pulmonary disease. Sonographic visualization of pericardial fluid in this setting mandates emergent thoracotomy (Fig. 42-14).

A chest radiograph should be obtained immediately in all cases of acute, blunt chest injuries. Although this study usually does not help diagnose cases of myocardial rupture, it notes the presence of other intrathoracic injuries (e.g., hemothorax, pneumothorax, and signs of possible aortic dissection). An increase in the size of the cardiac silhouette more commonly reflects preexisting disease or valvular incompetence with chamber enlargement caused by increased filling pressures. ECG changes may occur with myocardial injury, but these are often nonspecific for myocardial rupture. Early use of bedside echocardiography in the ED should be performed in any case of suspected cardiac rupture, pericardial tamponade, a previously undiagnosed murmur, or shock unexplained by other etiologies (e.g., exsanguination).

Management

When nonhospital medical personnel evaluate a patient who has sustained blunt chest trauma, they should concentrate on rapid transport and pay attention for any signs of pericardial tamponade. En route to the hospital, the possibility of a tension pneumothorax should be considered as well.

In the ED, treatment of patients with a myocardial rupture is directed toward immediate decompression of cardiac tamponade and control of hemorrhage. Péricardiocentesis may be effective in cases of a small rupture, but it is usually performed as a diagnostic or temporizing therapeutic procedure until surgical correction can be undertaken. Emergency thoracotomy and pericardiectomy may be required in the ED if the patient has rapidly deteriorating vital signs or a cardiac arrest. After emergency thoracotomy and pericardiectomy, the myocardial rupture should be controlled until the patient can be trans-
reported to the operating room for definitive repair. Hemorrhage from a ruptured atrium can often be controlled by finger occlusion or application of a vascular clamp. Insertion of a Foley catheter through the defect, followed by inflation of the balloon and traction on the catheter, may also control the bleeding. Ventricular rupture can usually be controlled by direct digital pressure or by suturing with nonabsorbable vascular sutures. Cardiopulmonary bypass is required in only 10% of successful repairs of myocardial rupture.\(^7\) Therefore, for patients with suspected myocardial rupture, it is appropriate to undertake emergency thoracotomy in institutions that have qualified surgeons but no immediate access to cardiopulmonary bypass.

**Prognosis**

Reported survival rates for patients with myocardial rupture and an intact pericardium vary widely. Although only a small number of survivors of ventricular rupture have been previously reported,\(^7\) a small case series reported that four out of a total of five patients with blunt cardiac rupture who arrived at the ED with vital signs ultimately survived.\(^7\) Most survivors of cardiac rupture are patients with atrial rupture, including one patient with multiple atrial tears. Most undergo surgical repair within 3 or 4 hours of injury.\(^7\) Approximately 60% of successful repairs have been performed more than 60 minutes after injury.

**Miscellaneous Cardiac Injuries**

The occurrence of intracardiac injuries that result from blunt chest trauma (e.g., septal defects or valvular injuries) is less common. Valve rupture may involve the chordae tendinae, leaflets, or papillary muscles. Involvement of the aortic valve is more common than involvement of the mitral or tricuspid valves. Mitral and tricuspid valve injuries associated with a pericardial laceration have been reported in a survivor of blunt chest trauma. The exact incidence of cardiac valvular injuries and septal defects is unknown. Serial echocardiography and monitoring of ECG changes as well as frequent auscultation may aid in earlier diagnosis of these lesions.

**Clinical Features**

The clinical presentation of these patients depends on which valve or septum is involved and whether coincident cardiac injuries are present. A complete rupture of the mitral valve usually results in immediate death. The clinical presentation of an incomplete rupture depends on the hemodynamic state of the patient. Cardiogenic shock is common. Findings of acute mitral insufficiency and rapidly developing pulmonary edema are usually predominant. A loud, harsh diastolic murmur with frank left heart failure suggests acute aortic insufficiency. If the patient is in a low output state, the associated thrills and murmurs of aortic or mitral insufficiency may not be appreciated. The signs and symptoms of tricuspid insufficiency that follow a rupture of that valve may be less dramatic or even minimal. Examination may reveal only a diastolic murmur and prominent V waves of the jugular venous pulsations.

Patients with isolated septal defects may have minimal symptoms of exertional dyspnea or severe progressive shock and pulmonary edema, depending on the size and location of the defect. Dysrhythmias and conduction defects are rare because the lower muscular septum is principally involved. The typical holosystolic murmur along the left sternal border is an important clue in diagnosing a ventricular septal defect, but it may not appear for days or months after the injury. Serial echocardiography and ultimately cardiac catheterization for both valvular and septal defects are necessary for a definitive diagnosis.

**Management**

The therapy selected depends primarily on how well the patient tolerates the insult. Many years may elapse before operative treatment is required. In cases of ventricular septal defects, a period of observation is valuable because there have been reports of the spontaneous closure of traumatic ventricular septal defects months after the injury when the defects and resultant shunt are small. Medical therapy commonly relieves the symptoms of congestive failure, but intractable or progressive heart failure or the development of pulmonary hypertension usually indicates the need for surgery.

**Penetrating Cardiac Injury**

Penetrating cardiac injuries are one of the leading causes of death in the setting of urban violence. Improvements in emergency medical services systems during the past few years along with an emphasis on rapid transport are responsible for an increasing number of cardiac injury patients arriving in impending or full cardiopulmonary arrest at busy urban trauma centers. The proportion of gunshot wounds versus stab wounds varies widely in reported case series, depending on the location of the trauma center.

The right ventricle is affected more often (43%) than the left ventricle (34%) due to its anterior anatomic location. The left or right atrium is affected in 20% of cases.\(^7,76\) One third of penetrating cardiac wounds affect multiple chambers, and survival is much worse in these cases. In 5% of cases, a coronary artery is lacerated, although these injuries usually involve a distal segment of the artery and rarely produce significant acute MI when they are ligated. More proximal coronary artery lacerations require coronary bypass.\(^76\) Rarely, the interventricular septal, a valve, papillary muscle, or chordae tendinae is lacerated, producing an acute shunt or valvular insufficiency. These lesions are poorly tolerated and can quickly produce massive pulmonary edema and cardiogenic shock.

Two conditions may occur after penetrating heart injury: (1) exsanguinating hemorrhage if the cardiac lesion communicates freely with the pleural cavity or (2) cardiac tamponade if the hemorrhage is contained within the pericardium. Patients with exsanguinating wounds frequently die before they reach medical attention, or they present with rapidly progressive hemorrhagic shock culminating in cardiac arrest. This presentation is most typically seen in patients sustaining gunshot wounds to the heart. These patients often require immediate resuscitation by ED thoracotomy if they meet the criteria listed in Box 42-3. Cardiac tamponade is a life-threatening condition but appears to offer some degree of protection and increased survival in patients with penetrating cardiac wounds.

**Acute Pericardial Tamponade**

**Epidemiology**

The reported incidence of acute pericardial tamponade is approximately 2% in patients with penetrating trauma to the chest and upper abdomen; it is rarely seen after blunt chest trauma. It occurs more commonly with stab wounds than with gunshot wounds, and 60 to 80% of patients with stab wounds involving the heart develop tamponade.\(^7\) Patients with acute pericardial tamponade can deteriorate in minutes, but many can be saved if proper steps are taken.
Indications for emergency department thoracotomy

**Penetrating Traumatic Cardiac Arrest**
- Cardiac arrest at any point with initial signs of life in the field
- Blood pressure <50 mm Hg systolic after fluid resuscitation
- Severe shock with clinical signs of cardiac tamponade

**Blunt Trauma**
- Cardiac arrest in the emergency department

**Miscellaneous**
- Suspected air embolus

**Anatomy/Pathophysiology**

The primary feature of a pericardial tamponade is an increase in intrapericardial pressure and volume. As the volume of the pericardial fluid encroaches on the capacity of the atria and ventricles to fill adequately, ventricular filling is mechanically limited and thus the stroke volume is reduced. This results in decreased cardiac output and ultimately diminished arterial systolic blood pressure and decreased pulse pressure. As little as 60 to 100 mL of blood and clots in the pericardium may produce the clinical picture of tamponade. Concomitantly, CVP rises because of the mechanical backup of blood into the vena cava.

Several compensatory mechanisms then occur. The heart rate and total peripheral resistance rise in an attempt to maintain adequate cardiac output and blood pressure. A less effective compensatory response, resulting in a greater rise of CVP, is an increase in venomotor tone caused by contractions of the smooth muscles within the wall of the vena cava.

The diagnosis of pericardial tamponade should be suspected in any patient who has sustained a penetrating wound or blunt trauma to the thorax or upper abdomen. One is never certain of the trajectory of the bullet or the length, force, and direction of a knife thrust upon initial evaluation. Obviously, wounds directly over the precordium and epigastrum are more likely to produce a cardiac injury resulting in tamponade than those in the posterior or lateral thorax. Nevertheless, it must be assumed that a penetrating wound, particularly a gunshot wound, anywhere in the thorax or upper abdomen may have injured the heart. Rapid bedside echocardiography, performed as part of the standard FAST exam, easily detects a pericardial effusion causing cardiac tamponade.

**Clinical Features**

Patients with cardiac tamponade may initially appear deceptively stable if the rate of bleeding into the pericardial space is slow or if the pericardial wound allows intermittent decompression. Other patients may complain primarily of difficulty breathing, which suggests pulmonary rather than cardiac pathology.

The physical findings of pericardial tamponade are hypotension, distended neck veins, and, rarely, distant or muffled heart tones. This so-called Beck’s triad is sometimes difficult to demonstrate clinically, especially in the midst of a major resuscitation with concomitant hypovolemia.

Although the most reliable signs of pericardial tamponade are an elevated CVP (>15 cm H₂O) in association with hypotension and tachycardia, bedside echocardiography performed as part of the FAST exam rapidly identifies pericardial tamponade and has largely replaced the use of CVP measurements to make the diagnosis. Echocardiography also distinguishes pericardial tamponade versus tension pneumothorax when the triad of elevated CVP, hypotension, and tachycardia is present.

Acute pericardial tamponade may be seen with three distinct clinical pictures. If the hemorrhage is confined to the pericardial space, the patient is initially normotensive but will have a tachycardia and elevated CVP. If untreated, most of these patients go on to develop hypotension. If significant hemorrhage has occurred outside the pericardial sac, either through a tear in the pericardium or from associated trauma, the clinical picture is that of hypovolemic shock with hypotension, tachycardia, and a low CVP. If the CVP rises to a level of 15 to 20 cm H₂O with volume replacement and hypotension and tachycardia persist, the presence of a pericardial tamponade must be considered. One must also consider other causes, such as a tension pneumothorax, Valsalva maneuver, or pulmonary edema secondary to fluid overload.

The third clinical picture is that of an intermittently decompressing tamponade. In this case, intermittent hemorrhage from the intrapericardial space occurs, decompressing and partially relieving the tamponade. The clinical picture may wax and wane depending on the intrapericardial pressure and volume and total blood loss. In general, this condition is compatible with a longer survival than are the first two clinical presentations.

Pulsus paradoxus is defined as an excessive drop in systolic blood pressure during the inspiratory phase of the normal respiratory cycle. This sign may be an additional clue to the presence of pericardial tamponade, but it is often difficult to measure during an intensive resuscitation or in the presence of shock.

**Diagnostic Strategies**

**Ultrasound.** Ultrasound (US), which is now widely available in EDs throughout the world, enables rapid, accurate, and noninvasive diagnosis of pericardial tamponade. This study can be performed at the bedside in the ED during the initial resuscitation of the patient as part of the FAST exam. Although the sonographic definition of tamponade is the simultaneous presence of pericardial fluid and diastolic collapse of the right ventricle or atrium, the presence of pericardial fluid in a patient with chest trauma is highly suggestive of pericardial hemorrhage (see Fig. 42-14). An indirect sonographic sign of tamponade is the demonstration of a dilated inferior vena cava in a hypotensive patient. EDs performing cardiac ultrasonography using subcostal and long parasternal views have reported a sensitivity of 98.1% and a specificity of 99.9% for the detection of pericardial effusion. Because US is noninvasive and extremely accurate, its immediate availability in the initial phase of a major trauma resuscitation can be very helpful in detecting pericardial fluid before the patient deteriorates hemodynamically.

**Electrocardiography.** Many ECG changes of pericardial tamponade have been described in the literature, but few are diagnostic, and each is more likely to be seen with chronic rather than acute tamponade. Electrical alternans has been reported to be a highly specific marker of pericardial tamponade. Electrical alternans is an ECG change in which the morphology and amplitude of the P, QRS, and ST-T wave in any single lead alternate in every other beat (Fig. 42-15). The postulated cause is the mechanical oscillation of the heart in the pericardial fluid, which is called the swinging heart phenomenon. In uncomplicated pericardial effusion, the heart swings back and forth but returns to approximately the same position before the next systole. Electrical alternans does not occur in this situation.
Echocardiographic studies have revealed that when fluid accumulates to a critical extent and cardiac tamponade ensues, the frequency of cardiac oscillation may abruptly decrease to half the heart rate. The cardiac position will alternate, with the heart returning to its original position with every other beat, and electrical alternans may be seen. Electrical alternans, when present, is pathognomonic for tamponade. However, it is much more common in chronic pericardial effusions that evolve into a tamponade, and it is rarely seen in acute pericardial tamponade.

Radiography. The radiographic evaluation of the cardiac silhouette in acute pericardial tamponade generally is not helpful, unless a traumatic pneumopericardium is present. Because small volumes of hemopericardium lead to tamponade in the acute setting, the heart will typically appear normal. This is in contrast to the “water-bottle” appearance of the heart with chronic pericardial effusion. This latter condition is tolerated unless a traumatic pneumopericardium is present. Because prolonged ischemia and severe acidosis often result in postresuscitation myocardial depression with ineffective contractions while preparations are under way to quickly transport the patient to the operating room for definitive therapy. If pericardiocentesis is unsuccessful or the clinical status deteriorates, and if acute pericardial tamponade remains important in the differential diagnosis, thoracotomy should be performed as quickly as possible. Patients with penetrating cardiac injury invariably require surgical repair. The location (operating room vs. ED) and timing (immediate vs. urgent) depend on the patient’s clinical status.

Emergency Department Thoracotomy. Emergency department thoracotomy (EDT) is a drastic, dramatic, and potentially life-saving procedure in which emergency physicians should be proficient. Although the procedure is not described in detail here, a few technical points merit discussion. A left lateral incision is preferred because it is rapidly accomplished; allows the best exposure of the heart, aorta, and left hilum; and facilitates open cardiac massage and internal defibrillation. With right-sided or multiple injuries, it may be necessary to extend the incision across the sternum and right chest wall, creating a “clamshell” incision. The internal mammary arteries need to be ligated if this maneuver restores effective perfusion. After the heart is sufficiently exposed, the pericardium is incised anterior to the phrenic nerve. Release of a tamponade may rapidly restore cardiac output. The heart is then delivered through the pericardium and penetrating wounds are identified.

There are several alternatives for repairing cardiac wounds. Small wounds can be compressed by digital pressure to control bleeding in route to the operating room. If the injury is quite large, balloon tamponade can be achieved by applying gentle traction on a Foley catheter inserted into the wound with the balloon inflated with saline. This can temporarily stop the hemorrhage to allow suture repair of the injury (cardiorrhaphy) or to gain time while the patient is transferred to the operating room for a more definitive surgical procedure. Lacerations of the atria can be temporarily controlled with a vascular clamp.

Suture of cardiac wounds over pledgets is the time-honored and effective technique but is technically more difficult and more time-consuming. The use of a monofilament suture, such as 2-0 prolene, is recommended. Some trauma surgeons recommend stapling cardiac wounds with standard skin staplers since this technique has been shown to be much quicker and equally effective in closing these wounds, and there is also a report on the use of a collagen mesh attached with fibrin glue mesh to rapidly repair a ventricular laceration.

Care must be taken to avoid ligating coronary arteries during repair. Direct insertion of a large-bore catheter (e.g., a 5-F catheter) into the left atrial appendage provides a route for rapid infusion of fluids. If the heart is empty or the patient fails to respond to rapid fluid administration, the aorta is cross-clamped to divert cardiac output to the brain and heart. Prolonged ischemia and severe acidosis often result in postresuscitation myocardial depression with ineffective contraction and diminished cardiac output.

Indications for Emergency Department Thoracotomy. Although it is often tempting to perform EDT on all traumatic arrest victims pre-
senting to the ED, there are clearly cases in which it has virtually no chance of salvaging the patient. In addition, EDT is costly; requires the undivided attention of all personnel in the ED, diverting care from other more salvageable critical patients; and poses a risk to ED personnel for injury from needle sticks and other blood-contaminated exposures. Consequently, guidelines have been established for performing EDT to restrict the procedure to patients with some chance of achieving a neurologically functional outcome (see Box 42-3).

Patients with penetrating trauma with signs of life in the field, even if only electrical activity on cardiac monitor or agonal respirations, are candidates for EDT if transport times are less than 10 minutes.

**Prognosis**

After penetrating wounds to the heart, several factors adversely affect survival, including gunshot wound mechanisms and wounds that involve the left ventricle, multiple cardiac chambers, intrapericardial great vessels, or one or more coronary arteries. The factors favorable to survival include stab wound mechanisms with minor perforations, isolated right ventricular wounds, a systolic blood pressure greater than 50 mm Hg on arrival at the ED, and the presence of cardiac tamponade.

Survival rates after EDT have been correlated with the mechanism and location of injury, field and transport times, the duration of arrest, and the physiologic status of the patient in the out-of-hospital and hospital settings. Although reported survival rates from EDT vary widely, they are consistently higher in victims with isolated cardiac injuries secondary to stab wounds versus gunshot wounds.

A meta-analysis of the literature found that EDT had an overall survival rate of 7.4%, with normal neurologic outcomes noted in 92.4% of surviving patients. Survival rates for mechanism of injury were 9% for penetrating injuries and 1% for blunt injuries. When penetrating injuries were further separated, the survival rates were 17% for stab wounds and 4% for gunshot wounds. The presence of pericardial tamponade is a favorable prognostic finding.

**Blunt Aortic Injury**

**Epidemiology**

Blunt aortic injury is a life-threatening injury, usually resulting from either unrestrained frontal collisions or violent lateral blunt impact to the chest. Blunt aortic injury includes a spectrum of lesions, ranging from a small intimal tear to frank rupture, which usually cause rapid lethal hemorrhage. The most common sites of injury are the aortic isthmus and the ascending aorta just proximal to the origin of the brachiocephalic vessels. Sixty to 90% of patients with blunt aortic injury die at the site of accident or within hours of hospital admission. However, an increasing number of patients arrive at a treatment facility because of improvement in out-of-hospital care, more aggressive resuscitation in the field, and rapid transportation to a trauma center. The early survival rate of such patients depends on the initial resuscitation and/or the timeliness and correct choice of the diagnostic procedures. A rapid and accurate diagnosis is thus mandatory to optimize treatment and maximize patient survival.

**Anatomy/Pathophysiology**

Blunt aortic injury encompasses various histologic lesions. Minor blunt aortic injuries (grade 1, intramural hematoma or limited intimal flap) and major blunt aortic injuries (grade 2, subadventitial rupture or modification of the geometric shape of the aorta; and grade 3, aortic transection with active bleeding or aortic obstruction with ischemia) can be differentiated by TEE. Whereas minor blunt aortic injuries appear to have a good prognosis, major blunt aortic injuries involve the entire depth of both the intimal and the medial layers and may lead to adventitial rupture, resulting in sudden death at the scene of the accident or during the first hours of hospitalization. Several theories about the mechanism of aortic rupture have predominated in the literature. The descending thoracic aorta is relatively fixed and immobile because of its tethering by intercostal arteries and the ligamentum arteriosum. With sudden deceleration, the more mobile aortic arch swings forward, producing a shearing force or “whiplash effect” on the aorta at the isthmus. A bending stress at the isthmus, created by sudden lateral oblique chest compression, may also result in rupture by causing flexion of the aortic arch on the left mainstem bronchus and the pulmonary artery. It has been suggested that the forces created by the whiplash effect or lateral oblique compression may not be sufficient to provoke aortic tears. It is now postulated that those injuries may be caused by inferior and posterior rotation of anterior thoracic osseous structures (manubrium, first rib, and medial clavicles), pinching and shearing the interposed aorta as they strike the vertebral column.

Rupture of the ascending aorta just distal to the aortic valve likely occurs through a different mechanism. At the time of rapid deceleration and chest compression, the heart is displaced into the left posterior chest, which causes a shearing stress just above the aortic valve. A sudden increase in intraaortic pressure, “the waterhammer effect,” may also cause an explosive rupture of the aorta at this location. Involvement of the coronary ostia with coronary artery occlusion may occur in association with tears to the ascending arch. The intraluminal pressure tolerance of the aorta may be exceeded in a high-speed motor vehicle crash. It is likely that a combination of the preceding mechanisms accounts for the multiple aortic ruptures that have been found in 20% of traffic accident victims examined at autopsy.

A total of 80 to 90% of aortic tears occur in the descending aorta at the isthmus, just distal to the left subclavian artery (Figs. 42-16 and 42-17). Other less common sites of involvement are the ascending aorta, the distal descending aorta at the level of the diaphragm, the midthoracic descending aorta, and the origin of the left subclavian artery. Although ruptures of the ascending aorta are much less common than those of the descending aorta, they have a 70 to 80% incidence of associated lethal cardiac injuries. This is in contrast to ruptures at the isthmus, which have a 25% incidence of associated cardiac injuries. Lethal cardiac injuries commonly include pericardial tamponade, aortic valve tears, myocardial contusion, or coronary artery injuries. Passenger ejection, pedestrian impact, severe falls, and crush injuries commonly result in ascending thoracic aortic ruptures. Survival long enough to be evaluated in the ED is rare among patients who sustain an ascending aortic rupture.

Aortic rupture may occur from causes other than high-speed motor vehicle crash deceleration. Rupture has been documented as a complication of external cardiac massage and has been known to occur after fracture-dislocations of the thoracic spine, presumably as the result of direct shearing force. Vertical deceleration injuries resulting from falls can cause a rupture of the ascending aorta by producing an acute lengthening of the ascending aorta. This is the likely mechanism responsible for aortic rupture in the setting of airplane and elevator accidents. Direct kicks by animals, crush injuries, sudden burial by landslide, and air bag deployment have also been reported.
Figure 42-16. Aortogram shows tear in aorta (arrows) at the most common location, at or just distal to takeoff point of left subclavian artery, which is not visualized.

Figure 42-17. A, Follow-up aortogram of patient in Figure 42-16. Arch study with catheter in ascending aorta. Tear in aorta (arrows) distal to the left subclavian artery is seen with dissection and extravasation of contrast material. B, Reverse image.

as causes of aortic rupture. Direct compression of the compliant thorax has been postulated to contribute to aortic rupture in children. Displaced fractures of the sternum, ribs, and clavicle have also been shown to directly lacerate the aorta.

Clinical Features

The possibility of aortic disruption must be considered in every patient who sustains a severe deceleration injury. This is especially true if the automobile was moving in excess of 45 mph or if there is evidence of severe blunt forces to the chest (e.g., from a damaged steering wheel). In the case of any moderate- or high-speed motor vehicle accident, it is imperative that paramedics carefully evaluate the extent of damage to the vehicle, the complaints of the victims, and the physical manifestations of blunt chest trauma. This information should be promptly relayed to the emergency physician.

Despite the severe nature of the injury, the clinical manifestations of an aortic rupture are often deceptively meager. Associated pulmonary, neurologic, orthopedic, facial, and abdominal injuries are commonly present. Coexisting injuries can mask the signs and symptoms of an aortic injury or divert the physician’s attention away from the more lethal aortic rupture. The absence of any external evidence of a chest injury does not eliminate the possibility of an aortic tear. One third to one half of patients reported in the literature have no external signs of chest trauma.

The most common symptom is interscapular or retrosternal pain. It is often found in nontraumatic aortic dissection but is present in only 25% of patients with a traumatic aortic disruption. Other symptoms described in the literature but uncommonly present include dyspnea resulting from tracheal compression and deviation, stridor or hoarseness caused by compression of the laryngeal nerve, dysphagia caused by esophageal compression, and extremity pain caused by ischemia from decreased arterial flow.

Clinical signs are uncommon and nonspecific. Generalized hypertension, when present, may be an important clinical sign. Sympathetic afferent nerve fibers, located in the area of the aortic isthmus, are capable of causing reflex hypertension as a response to a stretching stimulus. A less common clinical finding is the acute onset of upper extremity hypertension, along with absent or diminished femoral pulses. This pseudo-coarctation syndrome has been reported to occur in up to one third of these patients and is attributed to compression of the aortic lumen by a periaortic hematoma.

The presence of a harsh systolic murmur over the precordium or posterior interscapular area may be heard in up to one third of patients. The murmur is thought to result from the turbulent flow across the area of transection. A less commonly encountered physical finding is a swelling at the base of the neck caused by the extravasation of blood from the mediastinum, which results in an increased neck circumference or a pulsatile neck mass. Other clinical signs suggestive of aortic rupture include lower extremity pulse deficit and lower extremity paralysis. Initial chest tube placement output in excess of 750 mL is also suggestive of aortic rupture, especially if the hemothorax is left sided. However, the physical examination is neither sensitive nor specific for aortic injury, preventing accurate diagnosis without ancillary studies.

Diagnostic Strategies

Chest Radiography. Radiography of the chest is a valuable tool when aortic rupture is suspected. Many patients have died because the presence and significance of radiographic findings were not appreciated. An increase in the width of the superior mediastinum is the most sensitive sign and is found in 50 to
Figure 42-18. Anteroposterior radiograph of the chest showing wide mediastinum (arrows).

Figure 42-19. Chest CT demonstrating periaortic hemorrhage and an intimal flap.

92% of aortic ruptures (Fig. 42-18).94,95 However, specificity of this radiologic sign is as low as 10%.

Mediastinal widening may be caused by venous bleeding from a clavicle, thoracic spine, or sternal fracture; pulmonary contusions; a previous mediastinal mass; a misplaced CVP catheter; or magnification caused by the anteroposterior and supine position of a portable chest radiograph. Hence, the sign is not pathognomonic for aortic rupture.

Commonly cited guidelines for abnormal mediastinal widening include a mediastinal width greater than 6 cm in the erect posteroanterior film, greater than 8 cm in the supine anteroposterior chest film, or greater than 7.5 cm at the aortic knob or a ratio of mediastinal width to chest width greater than 0.25 at the aortic knob. There is disagreement regarding the reliability of these parameters in confirming or excluding aortic rupture. A subjective interpretation of mediastinal widening is more reliable than direct measurement of mediastinal width.95 Positioning of the patient and the degree of inspiration are important factors in assessing the mediastinum. Every effort should be made to obtain a standard upright inspiratory posteroanterior film, if clinically feasible, before a mediastinum is declared abnormal to avoid false-positive interpretations.

Current literature is replete with various diagnostic radiologic criteria thought to be sensitive indicators of aortic rupture.96,97 Several authors have shown that an interpretation of widened mediastinum and an obscured aortic knob are the most reliable signs of aortic rupture. The opacification of the clear space between the aorta and the pulmonary artery, displaced nasogastric tube, widened paratracheal stripe, or widened right paraspinal interface is thought to provide the most specific evidence for aortic rupture.94,96,97 Others believe that deviation of the nasogastric tube to the right in combination with depression of the left main stem bronchus below 40 degrees from the horizontal is the most reliable sign positively associated with the diagnosis.

Other reported radiologic signs of a ruptured aorta include left hemithorax, obliteration of the medial aspect of the left upper lobe apex (left apical pleural cap), deviation of the trachea to the right, and multiple rib fractures. Fractures of the first and second ribs, once classically described as highly suggestive of aortic injury, do not appear to be associated with increased risk compared with that of patients without these fractures.

Although previous reports suggested that a negative chest radiograph is highly predictive of a normal aortogram, several studies have challenged this widely held belief.94,96,97 The sensitivity of a negative chest radiograph (i.e., normal mediastinum) is limited. Several authors recommend liberal use of helical chest CT scanning in patients with high-speed deceleration mechanisms of injury. Reported rates of false-negative CXRs with no mediastinal widening in patients with proven aortic injury vary from 0 to 45%.94,96,97

Chest CT Scan. Chest CT scans have largely replaced the need for aortography to detect aortic rupture.98-104 The development of the new multidetector helical CT scans in the early 1990s revolutionized trauma radiology with its speed and superior definition, thereby largely negating the negative results obtained with conventional scans. New helical CT scans have almost 100% sensitivity and specificity for rapidly detecting aortic injury while requiring only intravenous contrast administration (Fig. 42-19). A normal aortic contour on CT, even in the presence of a mediastinal hematoma, has been shown to be highly accurate in excluding thoracic aortic disruption.98-104

A chest CT scan with intravascular contrast offers a number of advantages over aortography. It is noninvasive, provides significantly more information on other thoracic injuries than chest radiography, and can be performed more rapidly than angiography. At most centers, an immediate chest CT scan is readily available. In addition, in the group of patients with a widened mediastinum, CT evaluation may be useful in evaluating not only the aorta but also the spine because spinal fractures may be the cause of a widened mediastinum. It is now recommended that all patients with a mechanism of injury suggestive of potential aortic injury should undergo CT evaluation of the mediastinum, irrespective of chest radiographic findings.99

Transesophageal Echocardiography. TEE is an alternative method to CT scanning or aortography for establishing the diagnosis of aortic rupture.105-107 It offers a number of advantages over other diagnostic studies: It is fast, does not require intravenous contrast or radiation exposure, provides concomitant evaluation of cardiac function, and can be performed in the ED. Sedation is necessary to avoid hypertension while inserting the probe. TEE is contraindicated in patients with esophageal injury.

TEE allows identification of an intimal flap, as well as a periaortic hematoma (Fig. 42-20). When only a monoplane TEE is used, the upper portion of the ascending aorta represents a blind zone because of the interposition of the air-filled...
intimal or medial lesions of the thoracic aorta.108 and is more sensitive than CT for the identification of tion, TEE also allows the diagnosis of associated cardiac inju -

Figure 42-20. Transesophageal echocardiogram shows periaortic hemorrhage and aortic dissection (arrows). AO, aorta; PA, periaortic.

In patients with severe blunt chest trauma, TEE and CT have been found to have similar diagnostic accuracy for the identification of surgical acute traumatic aortic injury. In addition, TEE also allows the diagnosis of associated cardiac injuries and is more sensitive than CT for the identification of intimal or medial lesions of the thoracic aorta.108

Aortic repair may be feasible based on TEE alone, but aortography is still needed when TEE results are equivocal, when TEE is not tolerated or contraindicated, or when other suspected vascular injuries require evaluation by arteriography.109

Intravascular Ultrasound. Intravascular US has been described in the detection of subtle injuries to the aorta. This modality involves a small ultrasound probe that is inserted through the femoral artery and guided up the aorta. Currently, availability is limited to a few trauma centers because the technique requires sophisticated equipment and is performed in the operating room or angiography suite. Preliminary data suggest that intravascular US is extremely sensitive and specific in detecting blunt aortic injury.109

Aortography. Aortography, long considered the gold standard for establishing the diagnosis of aortic disruption, has been replaced almost completely by high-resolution helical CT scanners.106 The major objective for patients with a ruptured aorta is the early recognition of the lesion before adventitial disruption and exsanguination. Multiple aortic tears occur in 15 to 20% of cases, necessitating precise anatomic localization of these injuries. Before the widespread availability of helical CT scanners, aortography was recommended not only for patients with a widened mediastinum but also for those who had sustained significant blunt chest trauma and who had any of the radiologic signs previously mentioned. An aggressive approach is particularly warranted in elderly patients.

Aortography should be delayed in patients with more immediate life-threatening injuries to the abdomen, pelvis, and head. In circumstances in which aortography must be delayed, it is important to provide medical management and maintain the systolic blood pressure below 120 mm Hg with antihypertensive agents.111

High-quality aortography can be performed with the aid of a rapid film changer by directly injecting the contrast medium into the root of the aorta through a catheter. The procedure involves a risk of further damage to the aorta or other ruptured vessel if the catheter crosses the site of the injury; however, this risk can be reduced by using meticulous technique, a soft-tipped C-curve guidewire, and fluoroscopy. Simultaneous coronary angiography is often indicated, particularly in patients with an aortogram that shows a tear in the ascending aorta, because involvement of the coronary ostia by the dissection or the presence of significant arteriosclerotic disease may warrant coronary artery bypass grafting together with surgical repair of the aorta.

As surgeons have gained more experience with the diagnostic capabilities of helical CT scanning, the need for preoperative angiography has declined. Aortography should now be reserved for high-risk patients with indeterminate helical chest CT scans.99,110

Management

Out-of-Hospital. In the out-of-hospital care of any patient who has sustained blunt chest trauma, evaluation for possible aortic rupture should concentrate on identifying a mechanism of injury compatible with aortic rupture and treating hypotension, tension pneumothorax, and pericardial tamponade. Immediate communication of the patient’s condition and expeditious transport to a trauma center will increase the patient’s chance for survival.

Emergency Department. Because of the ever-present risk of sudden free rupture and exsanguination, repair of the lesion should be performed as soon as the diagnosis is made. Management of the patient with multiple injuries who has documented rupture of the thoracic aorta depends on the nature of associated injuries. Surgical repair of the aortic rupture should be delayed in the presence of life-threatening intracranial or intra-abdominal injury or profuse retroperitoneal hemorrhage.99 Consideration for delay of the procedure should be made for patients at high risk for infection (e.g., those who have extensive body surface burns, contaminated large open wounds, established sepsis, or severe respiratory insufficiency caused by thoracic trauma).

Careful regulation of blood pressure is mandatory until definitive surgical repair can be performed. If operative repair is delayed, the systolic blood pressure should be maintained between 100 and 120 mm Hg. The objective of lowering the blood pressure is to decrease the shearing jet effect of an elevated pulse pressure, thus decreasing the possibility of continued adventitial dissection and subsequent free rupture.111

Esmolol, a short-acting titratable beta-blocker, may be ideally suited for this purpose because, unlike nitroprusside sodium, it decreases the pulse pressure and minimizes the shearing effect on the intact adventitia of the aorta. If blood pressure is not adequately controlled, nitroprusside sodium can be added as a second agent after the pulse pressure has been decreased with a short-acting beta-blocker.

Surgical Techniques

Many surgical techniques have been described since the first successful repair by Passaro and Pace in 1959.112 In those patients who survive operative repair, paraplegia due to spinal cord ischemia has been a significant complication,
traditionally affecting as many as 10 to 20% of such patients.\textsuperscript{113,114} The major variable thought to be related to spinal cord ischemia and subsequent development of paraplegia has been aortic cross-clamp times.\textsuperscript{115} Blunt aortic injury ranges from a simple tear (usually distal to the origin of the subclavian artery) to complex injuries involving the proximal aorta and branch vessels.

Many surgeons have reported the use of cardiopulmonary bypass techniques in surgical repair to allow for distal spinal cord perfusion with significantly reduced incidence of paraplegia.\textsuperscript{115-117} This is especially true for patients with complex aortic injuries, for which the aortic cross-clamp times are typically prolonged.\textsuperscript{113}

The pathologic condition found dictates the type of repair. A synthetic graft is often required because of extensive tension on the vessel walls or jagged torn ends of the vessel. Data on successful primary repair of aortic disruption are encouraging. The procedure requires less operative time and has a lower potential infection risk, blood loss through a prosthesis is avoided, the possibility of pseudoaneurysm formation is eliminated, and secondary embolism arising from mural thrombosis is avoided. Multiple tears of the descending thoracic aorta have been successfully repaired using the primary suture technique. Direct end-to-end anastomosis appears to be most feasible in the younger population.

For patients who arrive at the hospital alive but who have descending thoracic aortic injuries, the incidence of mortality during surgery ranges from 20 to 30%, and the paraplegia rate is 5 to 7%.\textsuperscript{113,118-120} Younger patients have the highest survival rate. Mortality is related to the presence or absence of extensive dissection and to the preoperative condition of the patient.

There is a growing body of evidence demonstrating the safety and efficacy of endovascular repair of traumatic aortic tears. This involves the use of a stent placed through a femoral or iliac artery approach. Preliminary data indicate that success rates and complication rates are comparable if not better than those of traditional open surgical repairs and that the risk of major surgery and subsequent paraplegia from prolonged aortic clamping is significantly reduced with endovascular repair. Emerging literature suggests that endovascular repair with stenting is replacing open repair as the treatment of choice for blunt aortic injury.\textsuperscript{119,125}

\section*{ESOPHAGEAL PERFORATION}

\subsection*{Epidemiology}

Perforation of the esophagus has been called the most rapidly fatal perforation of the gastrointestinal tract because death is almost ensured if the diagnosis is delayed more than 24 hours.\textsuperscript{126} The classic description of esophageal perforation resulting from forceful vomiting was published in 1724 by Boerhaave, between 1724 and 1744, and 1941, the occurrence of Boerhaave’s syndrome was almost uniformly fatal.\textsuperscript{127} In 1941, the first successful surgical treatment, a drainage procedure, was reported, and in 1947 the first successful closure of a ruptured esophagus was described. Since then, improved surgical techniques, a greater physician awareness leading to a more prompt diagnosis, the availability of more effective antibiotics, and better general supportive measures have reduced the mortality to approximately 20%.\textsuperscript{128} Mortality data cited for perforation are affected by several variables, such as location (with perforations of the thoracic segment having the highest mortality rate), mechanism of injury, time elapsed between injury and diagnosis, the presence of preexisting esophageal disease, and general health of the patient.

\subsection*{Anatomy/Pathophysiology}

The anatomic feature responsible for the prolonged morbidity and high mortality associated with esophageal perforation is the lack of an esophageal serosal covering that allows perforation at any level direct access to the mediastinum. Perforations in the upper or cervical esophagus enter the retropharyngeal space, where fascial planes extend from the base of the skull to the bifurcation of the trachea. Perforations in the midesophagus and lower esophagus enter directly into the mediastinum. Only the thin mediastinal pleura prevents free access to the entire pleural cavity, and this barrier is commonly overcome by continued drainage and the massive exudative inflammatory reaction induced by chemical and bacterial mediastinitis. When the mediastinal pleura is penetrated, the negative pressure generated by respiratory efforts tends to increase the soiling by promoting drainage from the gastrointestinal tract into the mediastinum and pleural space.

When esophageal rupture results from emetic pressure, as in cases of Boerhaave’s syndrome, the intrinsic weakness of the left posterior distal esophagus is important. Other areas (including cervical, midthoracic, and infradiaphragmatic sites) have been reported only rarely to rupture secondary to emesis. In addition, the esophagus has three areas of anatomic narrowing:\textsuperscript{128} the cricopharyngeal muscle near the esophageal introitus, the level at which the esophagus crosses the left main stem bronchus and the aortic arch, and the gastroesophageal junction. In the absence of a preexisting esophageal disease such as carcinoma, it is unusual for a perforation caused by a foreign body to occur anywhere other than at these three sites. Foreign bodies may cause perforation by direct penetration, pressure, or chemical necrosis.

\subsection*{Etiology}

The most common causes of an esophageal perforation are shown in Box 42-4.

\subsection*{Iatrogenic}

Most esophageal perforations are iatrogenic, most commonly as a complication of instrumentation (59% of all patients).\textsuperscript{126} The rigid endoscope is the most common offender, particularly when general anesthesia is used. Although use of the flexible endoscope has made this complication less likely, the total number of perforations has increased as more procedures are performed. Injuries tend to occur near either the cricopharynx or the cervical esophagus as the endoscope is inserted.\textsuperscript{129} Endoscopic procedures that are too vigorous in the presence of a corrosive burn or carcinoma are also a common cause of iatrogenic esophageal injury.

Esophageal dilation performed for benign or malignant strictures of the esophagus is the second most common iatrogenic cause of esophageal perforations.\textsuperscript{123} Increasing the dilator size too rapidly during these procedures may lead to perforation. The preexisting fibrotic process that resulted in the stricture

\end{tabular}
\end{center}
tends to scar the surrounding mediastinal tissues, however, limiting free access to the mediastinum provided by many other perforations. In the ED, nasotracheal or nasogastric intubations are the most common causes of iatrogenic perforation, with the perforation usually occurring in the pyriform sinus. In a closed claims analysis published in 1999, esophageal injuries by anesthesiologists were overwhelmingly associated with difficult intubations. Risk factors for a difficult airway include obesity, cervical arthritis, haste, and improper muscle relaxation. Claims involving airways that were classified as “nondifficult” involved other esophageal instrumentation, such as a nasogastric tube, esophageal dilator, or esophageal stethoscope. In all cases, esophageal injuries were more severe than any other type of airway injury sustained during airway maneuvers.

The use of an esophageal obturator airway was also associated with occasional esophageal trauma, specifically mid-esophageal perforation. Use of the esophageal obturator airway’s most recent successor, the laryngotracheal Combitube, does not seem to be associated with trauma more severe than occasional esophageal abrasions or contusions. Several cases of esophageal rupture secondary to compressed air have been reported, including two cases of pharyngoesophageal perforation secondary to gas in carbonated beverages and in tartaric acid-sodium bicarbonate mixtures administered to treat esophageal food impactions. Esophageal perforation has also been caused by placement of a cervical fixation device and secondary to the Heimlich maneuver.

**Foreign Bodies**

Foreign bodies can cause an esophageal injury by direct laceration, by pressure necrosis, or during endoscopic removal. Small perforations tend to seal without sequelae, but pressure necrosis or lacerating injuries provide ample access to the mediastinum. Foreign bodies usually lodge in the cervical esophagus, but if a distal stricture is present, this too is a common site. In children younger than 4 years, the cricopharyngeal narrowing is the usual point of foreign body impaction. After age 4 years, most objects pass this region and traverse the remaining normal esophagus. In adults, a foreign body impaction, especially in cases of repeated episodes, raises the possibility of a stricture and mandates further investigation.

In elderly patients, foreign bodies commonly enter the esophagus because of a loss of oral tactile sensation resulting from intoxication or a poorly fitting set of dentures. Inadequate dentures may also lead to the swallowing of large pieces of poorly chewed food. Other esophageal foreign bodies include sharp fish or chicken bones and corn chips that may impale the esophageal wall leading to eventual leakage.

**Caustic Burns**

Caustic burns of the esophagus occur from intentional or accidental ingestion of acid or alkali. There are two peaks of incidence: 1 to 5 years of age, when ingestion is usually of a small amount of material and accidental, and in the teens and 20s, when larger quantities are ingested during suicide attempts. Symptoms include hematemesis, respiratory distress, vomiting, drooling, or the presence of oropharyngeal lesions on physical examination. Perforation usually occurs during the latent granulation stage of the disease, approximately 4 to 14 days after ingestion.

The liquefaction necrosis classically resulting from strong alkali burns (pH > 12) is more likely to cause esophageal perforation than the coagulation necrosis resulting from strong acid burns (pH < 2). Individuals ingesting alkali substances with a pH less than 11.5 rarely sustain injuries more serious than superficial mucosal burns. Acid ingestions cause damage more frequently in the stomach than in the esophagus.

In treating a patient who has ingested a caustic substance, decontamination should involve only the rinsing of the mouth. Dilution of the substance with milk or water has been suggested; however, further liquid ingestion should be avoided if there is suspicion of perforation. Emesis, gastric lavage, and charcoal should be avoided.

Endoscopy within the first 6 to 18 hours may be used to determine the extent of the injury and to guide therapy. Antibiotics are reserved for patients with evidence of perforation, and steroids are suggested by some authors if the burns are circumferential or transmural. Other authors have shown that in the setting of large alkali ingestions, corticosteroids not only did not prevent the formation of esophageal stenosis but also increased the risk of other complications.

Although admission after significant ingestion is the rule, some authors suggest that in the setting of accidental ingestion in children and in the absence of symptoms, endoscopy and admission may not be indicated. Esophagoscopy is commonly undertaken to ascertain the presence or absence of esophageal injury. Advancing the esophagoscopy beyond the first burn in the esophagus increases the risk of perforation and is a common iatrogenic cause of esophageal perforation.

**Penetrating and Blunt Trauma**

Because of its well-protected position posteriorly, esophageal trauma occurs in approximately 5% of patients with injuries to the neck, but only 1% of blunt trauma victims, and it is usually not an isolated injury. In children, the most common cause of esophageal injury is the accidental ingestion of an object. In adults, the most common life-threatening problem in the ED was compromise of the airway. Most of these cases were handled using rapid sequence intubation, but a significant number did not prevent the formation of esophageal stenosis but also increased the risk of other complications.

If the patient’s condition is stable, a preoperative esophagram with a liquid-soluble agent should precede any endoscopy. Although chest and neck radiograph and CT may also be used to diagnose this injury, emergent bedside flexible endoscopy seems to be the test of choice to confirm negative findings on esophagography (especially in the setting of penetrating trauma). Operative repair is indicated in most of these injuries (>90%) and should be done as quickly as possible to avoid the development of fistulae, mediastinitis, or abscess formation.

Blunt traumatic injuries to the esophagus occur much less often than penetrating injuries. The pathophysiology and prognosis of blunt injuries to the esophagus are similar to those of spontaneous rupture or emesis. In some cases, rupture of the cervical esophagus has been reported in association with cervical spine fracture.
instantaneous and massive mediastinal contamination. The distal esophagus is the usual site of injury, with a longitudinal tear occurring in the left posterolateral aspect. More than 80% of these injuries occur in middle-aged men who have ingested alcohol and large meals.

In vitro, a tear similar to that seen in cases of Boerhaave’s syndrome requires a force of 3 to 6 psi, which may be generated in vivo by gastric pressure caused by the reverse peristalsis (seen with emesis) pushing against a closed cricopharyngeal muscle. The role of preexisting gastrointestinal disease in spontaneous rupture of the esophagus is unclear. Some authors emphasize its importance, whereas others report that 80% of esophageal ruptures occur in a previously normal esophagus. Less pressure is required to perforate a diseased esophagus. Approximately 25% of patients with Boerhaave’s syndrome have no history of emesis. Increases in intra-abdominal pressure resulting from blunt trauma, seizures, childbirth, laughing, straining at stool, and heavy lifting have all been reported to cause this injury.

**Diagnostic Findings**

The diagnosis of esophageal perforation is aided by consideration of clinical circumstances. In patients with classic Boerhaave’s syndrome, emesis is followed by severe chest pain, subcutaneous emphysema, and cardiopulmonary collapse. Development of these signs and symptoms after instrumentation of the esophagus or removal of an esophageal foreign body is relatively straightforward. One third of cases of perforated esophagus are atypical, however. Only a careful history and physical examination supplemented with appropriate laboratory and diagnostic studies enable the clinician to diagnose a subtle case at an early stage. When considering any of the diagnoses listed in **Box 42-5**, a perforated esophagus should also be considered.

**Clinical Features**

The most reliable symptom of an esophageal injury is pleuritic pain localized along the course of the esophagus that is exacerbated by swallowing or neck flexion (Fig. 42-21). Pain may be located in the epigastrium, substernal area, or back; usually worsens over time; and may migrate from the upper abdomen to the chest. As the infectious process worsens, dyspnea usually ensues.

The early physical signs of an esophageal perforation are sparse. As air and caustic contaminated material move through the esophageal tear into the mediastinum and pleural space, and before any subcutaneous air is palpable at the root of the neck, the mediastinal air may impart a nasal quality to the voice. Mediastinal air may surround the heart and produce a systolic crunching sound (Hamman’s crunch). As air and fluid move into the pleural space, signs of a hydropneumothorax or an empyema may develop. Eventually, the air travels into the subcutaneous tissues, dissecting into the neck, where subcutaneous emphysema may first become evident. This classic sign is present in only approximately 60% of patients, however, and in the absence of a tracheal injury, it may occur in only 30%. As the infectious and inflammatory process advances, the patient’s general appearance and vital signs begin to manifest the signs of cardiopulmonary collapse and sepsis with fever, cyanosis, hypotension, anuria, and eventually death.

**Box 42-5**

**Clinical Conditions That May Mimic Esophageal Perforation**

1. Spontaneous pneumomediastinum
2. Aortic aneurysm (thoracic)
3. Pulmonary embolus
4. Perforated peptic ulcer
5. Myocardial infarction
6. Pancreatitis
7. Mesenteric thrombosis
8. Cholecystitis
9. Pneumonia

Figure 42-21. **A**, Chest radiograph of a 36-year-old man with acute onset of pleuritic chest pain after forceful vomiting. **B**, Chest radiograph shows mediastinal and subcutaneous air typical of ruptured esophagus. Mediastinum is not yet widened, and there is no soilage of the pleural cavity.
Diagnostic Strategies

Laboratory studies provide largely nonspecific findings. If tested, the pleural effusion of esophageal perforation may show a high salivary amylase level and a low pH. The radiographic examination usually suggests the diagnosis of an esophageal perforation. The classic chest radiograph findings are as follows:

1. Mediastinal air with or without subcutaneous emphysema
2. Left-sided pleural effusion
3. Pneumothorax
4. Widened mediastinum

Lateral views of the cervical spine may reveal air or fluid in the retropharyngeal area that is characteristic of a cervical esophageal perforation but also is found when perforations in the lower parts of the esophagus release air or fluid that dissect superiorly (Fig. 42-22). Most patients exhibit one or more of these abnormalities at some point in the course of the illness, but radiographic evidence of the perforation may be absent early on.

The literature is not conclusive on whether insoluble barium contrast medium or water-soluble diatrizoate meglumine (Gastrografin) is the preferred initial study. Gastrografin does not obscure visualization with subsequent endoscopy, and it produces less mediastinal soiling than does barium. It is generally recommended that the initial study use this water-soluble agent; then, if no leak is shown, a barium study may be undertaken to better define the mucosal detail.

Endoscopy, similar to contrast studies, is not an infallible aid in establishing the presence or absence of an esophageal perforation. The size and location of the perforation and the skill of the endoscopist are important factors in the low incidence of false-negative studies. If the accuracy of the endoscopy is in doubt, an esophagogram should be performed.

Helical CT using dilute oral contrast has been reported as a safer, faster, and less manpower-intensive diagnostic exam.139

Management

Early diagnosis can best be accomplished if one is aware of the pathophysiology and clinical settings in which esophageal perforations occur. Time is crucial in minimizing the mortality and morbidity of this condition. If the diagnosis is strongly suggested or confirmed, management should include broad-spectrum antibiotics (covering oral flora), volume replacement, and airway maintenance.133 An emergency surgical consultation should be obtained because prognosis worsens as time passes, with mortality almost doubling in the first 12 hours.139

Although operative therapy is standard, nonoperative therapy is an option for patients with well-contained perforations, minimal mediastinal involvement, and without evidence of sepsis.131 In such cases, the patient is placed NPO for at least 72 hours, broad-spectrum antibiotics are initiated, and usually total parenteral nutrition treatment is begun. The use of nasogastric tubes should be discouraged because they may increase gastroesophageal reflux and worsen the contamination of the mediastinum.129,139

![Figure 42-22. Lateral view of the cervical spine revealing air in the retropharyngeal area.](image)

**KEY CONCEPTS**

- Even relatively minor chest wall injuries, such as rib fractures, may result in serious complications in elderly patients and patients with preexisting pulmonary disease.
- Children are more susceptible to pulmonary contusion because of greater compliance of the chest wall.
- Unless there are abnormalities on the initial ECG, there is no need to pursue the diagnosis of myocardial contusion with more sophisticated tests.
- Many patients with myocardial rupture or traumatic aortic rupture survive to reach the hospital and can be salvaged with rapid diagnosis and intervention.
- Pericardial tamponade can be diagnosed accurately before hemodynamic decompensation occurs by standard cardiac ultrasound performed by emergency physicians.
- Chest CT should be considered for patients with mechanisms of injury concerning for blunt aortic injury even in the presence of normal chest radiographs.
- Injury of the esophagus is relatively common with penetrating trauma of the chest or neck. Because the presentation is initially subtle and the potential complications are severe, the diagnosis of esophageal perforation must be actively pursued in cases in which the trajectory of the penetrating wound potentially involves the esophagus.
PERSPECTIVE

Background

The management of abdominal trauma should be approached in an organized, vigilant, and knowledgeable manner. Reliance on key clinical features and the timely use of diagnostic procedures significantly improves morbidity and mortality rates. Missed or delayed diagnoses remain the most serious pitfalls in the management of abdominal injuries.1

Penetrating Abdominal Trauma

Whether by accident or intention, penetrating trauma can result from a wide variety of weapons or instruments, and certain elements of therapy vary accordingly. The management of penetrating trauma has changed dramatically since 1960, when Shaftan introduced the concept of selective laparotomy and serial observations.2 Before that time, surgery was mandatory. The careful integration of physical examination and certain diagnostic procedures, notably local wound exploration (LWE), diagnostic peritoneal lavage (DPL), ultrasonography (US), computed tomography (CT), and laparoscopy, now provides the emergency physician and trauma surgeon with an accurate means of determining whether laparotomy should be undertaken. The approach varies according to the clinical status of the patient, the instrument responsible for injury, and the site of penetration. Nonoperative management has gained favor for both stab wounds and gunshot wounds (GSWs) with the intent of reducing the incidence of and morbidity from nontherapeutic laparotomies.3,4

Blunt Abdominal Trauma

Blunt trauma to the abdomen (BAT) is a supreme challenge to the emergency specialist’s clinical acumen. Historical data may be incomplete, absent, or presumptive. The symptoms and signs can be unreliable and obfuscated by head injury, alcohol, or other toxins. The likelihood of trauma to systems other than the abdomen adds further complexity, underscoring the need for a carefully organized approach.

Epidemiology

Blunt injuries carry a greater risk of mortality than penetrating injuries because they are more difficult to diagnose and are commonly associated with severe trauma to multiple intraperitoneal organs and extra-abdominal systems.

Penetrating Abdominal Trauma

Wounds from stabbing implements occur nearly three times more often than wounds from firearms, but the latter have a significantly greater associated mortality rate and are responsible for 90% of the deaths from penetrating trauma.3 The small intestine, colon, and liver are, successively, the most likely organs to sustain injury after penetrating trauma.3 The highest risk of death from penetrating injury occurs among African Americans in the 15- to 34-year-old age range, followed by Hispanic persons in that same age group. The rate for non-Hispanic whites is greatest at 75 years of age and older. The predominant intent is homicide among African Americans and suicide among non-Hispanic whites.6,7

The use of firearms in the United States contributes heavily to the morbidity and mortality associated with trauma. The current U.S. civilian population is the most heavily armed in history. Over 42 million U.S. households have firearms, and there are more than 57 million gun owners.8 The number of homicides committed with firearms exceeds the number of homicides resulting from all other forms of violence combined. More than 850,000 American civilians have been killed by bullets in this century alone, and GSWs continue to occur with an increasing incidence in major U.S. cities.9

Blunt Abdominal Trauma

The spleen is the organ most often injured, and in nearly two thirds of these cases, it is the only damaged intraperitoneal structure. The liver is the second most commonly injured intra-abdominal organ, and the intestine is the most likely hollow viscus to be damaged.

The automobile is the major cause of BAT. Motor vehicle crashes and auto-pedestrian crashes have been cited as causes in 50 to 75% of cases, blows to the abdomen in approximately 15% of cases, and falls in 6 to 9%.10-12

Pediatrics

Each year in this country, trauma results in approximately 22,000 deaths and accounts for $160 billion of health care expenditures for children to the age of 16 years. Nearly 10% of children admitted to pediatric trauma centers are proven to have abdominal injury, and this category follows only head and thoracic trauma as the cause of injury-related death.13 Blunt mechanism causes approximately 85% of pediatric injury, although penetrating violence is becoming a greater concern.
As is true with adults, motor vehicle crashes are responsible for most of the morbidity and mortality in cases of trauma in children. Auto-pedestrian accidents and falls out of cars cause a significant percentage of these.

Child abuse continues to gain attention, and deservedly so. It is both common and extremely harmful. Soft tissue, skeletal, and intracranial injuries are most likely, but abdominal injuries occur occasionally and are second only to head injuries as the cause of death. Children in the preverbal stage, generally those younger than 2 years of age, are at greatest risk. The history of trauma is extremely difficult to obtain because of the inability or fear of the child to communicate and the reluctance of parents to divulge information. Injuries inconsistent with the history provided or not in keeping with the child’s level of physical maturity should alert the physician to the possibility of child abuse.

**PRINCIPLES OF DISEASE**

**Anatomy and Physiology**

The abdominal cavity and its contents can be reached not only through the anterior abdominal wall and lower chest but also through the flank, back, and buttocks. Missiles can also lodge intraperitoneally after traversing proximal extremities. The *anterior abdomen* is defined as that region between the anterior costal margins to the groin creases. The *low chest* begins at the nipple line or fourth intercostal space anteriorly and the inferior scapular tip or seventh intercostal space posteriorly and then extends down to the inferior costal margins. The *flank* is between the anterior and posterior axillary lines bilaterally from the inferior scapular tip to the iliac crest. The *back* is between the posterior axillary lines, beginning at the inferior scapular tip and extending down to the iliac crest. The intraperitoneal cavity is vulnerable when penetration occurs as high as the fourth intercostal space anteriorly and the sixth or seventh laterally and posteriorly because the diaphragm can ascend to this level during expiration. Likewise, simultaneous thoracic abdominal penetration has been found in 20 to 40% of cases of abdominal thoracic trauma. Scrutiny of entrance and exit sites, as well as wound tracts, is imperative.

**Pathophysiology**

**Penetrating Abdominal Trauma**

The instruments responsible for penetrating injuries of the abdomen are varied. Knives, handguns, rifles, and shotguns are at the fore, but flying glass, scissors, arrows, pickets fences, horned animals, and the like, although less common, can cause pronounced morbidity as well. Certain impulse injuries caused by fences, stakes, or similar objects can be treated as stab wounds. Likewise, various propelled missiles from lawn mowers, chain saws, and other machinery or resulting from violent weather should be managed as GSWs.

Fragmentation injuries produced by grenades and bombs are rare in this country, but industrial explosions can produce similar injuries, which are best categorized as shotgun-type wounds. BAT from blast effect can coexist in this setting. More widespread acts of terrorism would increase the number of these injuries.

The liver, followed by the small bowel, is the organ most often damaged by stab wounds, in keeping with the surface area each of these structures presents. The frequency of organ injury caused by GSW is greatest for the small bowel, followed by the colon and then the liver. Typically, multiple organ injuries are sustained, notably perforations to bowel. This same pattern is seen in the pediatric patient.

### Stab Wounds

Knives are not the sole implements used in stabblings. Ice picks, pens, coat hangers, screwdrivers, and broken bottles, to name a few, have been used by assailants. Stab wounds to the abdomen occur most commonly in the upper quadrants, the left more commonly than the right. They are multiple in 20% of cases and involve the chest in up to 10% of cases. Most stab wounds do not cause an intraperitoneal injury, and the incidence varies with the direction of entry into the peritoneal cavity. Anterior stab wounds penetrate the peritoneum in approximately 70% of cases but inflict a visceral injury in only half of these. Lower chest wounds are associated with a 15% incidence of coincident intraperitoneal damage in addition to the expected high rate of diaphragmatic injuries. Abdominal entries from the flank and back have reported incidences of up to 44 and 15%, respectively. The organ injured cannot be well predicted by the site of entry in the abdominal wall. The liver and spleen are the viscera most commonly damaged.

### Gunshot Wounds

The science of ballistics is complex, but a few basic principles are helpful in understanding the pathophysiologic processes of these injuries. The magnitude of the injury is proportional to the amount of kinetic energy imparted by the bullet to the victim, according to the following equation:

$$E = \frac{7000 \text{ m} \cdot \text{v}^2}{2g}$$

*E* is the kinetic energy (in foot-pounds), *m* is the mass of the bullet, *v* is the velocity of the bullet (in feet per second), and *g* is gravitational acceleration (in feet per second). In other words, the degree of injury depends on the mass of the bullet and the square of its velocity. Additional factors that affect injury created by a missile include the resistance and viscoelastic properties of the tissue through which it passes, as well as the stability of the missile in this medium. Missile velocities are categorized as low (slower than 1100 ft/sec), medium (1100–2000 ft/sec), and high (faster than 2000–2500 ft/sec); the impact velocity is the most important determinant of wounding capability. The impact velocity depends on the distance between the firearm and the victim, the muzzle velocity, and various characteristics of the missile. At medium and high velocities, the missile has an explosive effect and creates a temporary passage in the tissue along its course. The size of this passage is directly proportional to the specific gravity of the penetrated tissue. This sudden formation of a tract displaces nearby organs and vascular structures, and bone and viscera may be fractured or torn without being directly struck by the missile. Several cases have been reported of an intraperitoneal injury caused by a bullet that remained extraperitoneal throughout its entire course. Solid viscera such as the liver and spleen are more vulnerable to this effect.

### High-Velocity Missiles

Wounds from high-velocity missiles involve additional problems. First, external contaminants tend to be dragged into the wound. Second, the closure of the tract immediately after the bullet’s passage may lead to an underestimation of tissue damage. Finally, high-velocity bullets can fragment internally. In fact, a missile at any velocity can fragment after contact with bone and cause additional multiple trajectories and injuries. Civilian wounds have usually resulted from low-velocity handguns, but unfortunately a trend toward more destructive weapons such as the .38 and .357 may be occurring.

### Shotgun Wounds

The shotgun was designed to strike a small, fast-moving target at close range. Because of the ballistic shape
of the individual pellets, a rapid falloff in velocity occurs, making this weapon ineffective in producing severe wounds at long distances. An initial muzzle velocity of 1300 feet per second drops to 950 feet per second within 20 yards, a decrease of 25%. At close range (<15 yards), however, the shotgun is extremely lethal.

The kinetic energy imparted to the victim depends on the pellet's size, the number of striking pellets, the type and amount of powder, and the barrel choke (constriction). The most important variable is the distance between the shotgun and the victim. At a distance of 10 yards, 19% of the pellets cluster in a 9-inch diameter circle if fired from a full choke (maximum constriction) barrel. At a distance of 20 yards, the circle is approximately double that diameter. Because the kinetic energy is proportional to the square of the velocity, a 25% loss of velocity at 20 yards results in a significant decrease in the damage produced by the blast.

Shotgun wounds were previously classified in three groups according to the range and pattern of distribution. More recently, classification has been according to the pattern of injury on the victim. Based on distance from the weapon to the victim, type I wounds involve a long range (>7 yards) and a penetration of subcutaneous tissue and deep fascia only. Type II wounds occur at a distance of 3 to 7 yards and may create a large number of perforated structures. Type III wounds occur at point-blank range (<3 yards) and involve a massive destruction of tissue. When categorized by pattern, type I wounds produce a spread greater than 25 cm; type II, 10 to 25 cm; and type III, less than 10 cm, respectively, in diameter. The tissue damage is proportional to the specific gravity and inversely proportional to the elastic properties of the affected organ. Thus, the liver is more vulnerable than the lungs to this injury. Close-range shotgun wounds, in addition to the shot, force external contaminants (e.g., clothing and parts of the shell wadding) into the wounds. Type III wounds carry a substantial mortality risk.

Blunt Abdominal Trauma

Several pathophysiologic mechanisms have been described to occur in patients with BAT. First, sudden and pronounced rises in intra-abdominal pressures created by outward forces can cause rupture or burst injury of a hollow organ. Lap-belt restraints produce such a mechanism. Second, the compres-

Artificial ventilation can lead to gastric distention, partic-

Iatrogenic Injuries. Although well intentioned, diagnostic and therapeutic efforts in patient care are not risk-free. Abdominal injuries may be sequelae of various medical procedures and in certain instances not only are extremely difficult to recognize but may contribute to or cause pronounced morbidity or death. Numerous procedures may cause an iatrogenic injury.

Tube thoracostomy has resulted in injury to the liver and spleen. These injuries may result from an unknown eleva-

A liver biopsy can lead to a hemoperitoneum or hemobilia. Endoscopic procedures of the bowel may cause a hollow viscus perforation and peritonitis, particularly when a biopsy is performed. Peritoneoscopy has been reported to cause small-bowel perforations and iliac vessel lacerations. Barium
enemas have an extremely low incidence of perforation but can be another cause of unexplained peritonitis and pneumoperitoneum.

**Pediatrics.** Congenital anomalies and intra-abdominal neoplasms may be first discovered after a history of blunt trauma. Coagulopathies (e.g., hemophilia) can contribute to the pathologic condition and complicate therapy after apparent minor trauma to the abdomen.

A child’s abdomen has poorly developed musculature and a relatively smaller anteroposterior diameter. These factors increase the vulnerability of a child’s abdominal contents to compression between a blunt anterior force and the solid posterior vertebrae. The rib cage is extremely compliant in children and less prone to fractures but nonetheless provides only partial protection against splenic and hepatic injuries.

The liver, spleen, and kidney are the organs most commonly damaged by blunt mechanism of all varieties, and the incidence of injury for each of these three solid viscera is roughly the same. Gastrointestinal tract perforation is not uncommon with blunt trauma, and these injuries may be isolated. In cases of nonaccidental trauma, those injuries seen most commonly are duodenal and small-bowel hematomas and perforations, pancreatic contusions, lacerations and pseudocysts, lacerations and rupture of the liver and spleen, and lacerations of mesenteric vessels.

### CLINICAL FEATURES

**History**

The patient’s history may be unobtainable, elusive, or temporarily deferred while resuscitative measures are carried out. When the situation permits and a reliable source is available, obtaining certain information is valuable.

The patient’s ability to relate the course of events may be compromised by head or spinal cord injury, alcohol intoxication, mental retardation, hysteria, and exposure to any number of toxins. At times, the trauma may have preceded the onset of symptoms by days or weeks and may have been forgotten or considered trivial by the patient. Witnesses at the scene, particularly paramedical personnel, often provide the most reliable data.

Knowledge of substance exposure or events that could interfere with the clinical evaluation of the patient is helpful. Alcohol or drug use, a head or spinal cord injury, and psychiatric problems are the most common among these factors. Appreciation of comorbid medical conditions, particularly cardiovascular disease and coagulopathies, optimizes fluid and blood component therapy. Finally, when a first responder care team or transferring hospital is involved, the patient’s vital signs, history, preadmittance course, and response to field fluids administered, and the vital signs during the course of treatment by first responders.

**Bullet Abdominal Trauma**

**Stab Wounds.** It is helpful to obtain information regarding the mode of injury from the patient, paramedic, or witnesses. The number of stabs inflicted, type and size of the instrument, posture of the victim relative to the direction of assault, estimated blood loss at the scene, time of injury, and response to fluids should be sought. A significant proportion of victims of stab wounds are found under the influence of alcohol or another drug. This state can make obtaining an accurate history a futile effort and further compromise the validity of symptoms and signs.

**Gunshot Wounds.** As initial stabilization measures are instituted in the emergency department (ED), the emergency physician can elicit certain facts that can contribute greatly to the evaluation of the patient. These include the weapon used, its distance from the victim when shot, the position of the victim in relationship to the weapon when fired, the suspected number of shots, the blood loss at the scene, the amount and type of field fluids administered, and the vital signs during the course of treatment by first responders.

**Penetrating Abdominal Trauma**

**Assessment and management of abdominal injuries in children are based on the same principles as those used in adults. The symptoms and signs are similar and in alert, cooperative patients are valuable. Age-related difficulties in communication, fear-induced uncooperative behavior, or a concomitant head injury, however, make the clinical examination less reliable. In cases of unexplained abdominal tenderness or peritonitis, it is important to inquire about vaginal bleeding or discharge and rectal bleeding and to examine the rectum and vagina for foreign bodies. Such objects may be inserted by inquisitive children or by adults during acts of child molestation.**
Physical Examination

Abdominal trauma provokes a wide spectrum of presentations that range from seemingly insignificant symptoms and signs to severe shock and coma. Evidence of abdominal tenderness, peritoneal irritation, gastrointestinal hemorrhage, and hypovolemia not attributable to extra-abdominal causes represents most of the signs suggestive of an intraperitoneal injury. These signs may be initially absent or obscure, and careful attention to the abdomen with serial examinations can aid in making an early, accurate diagnosis.

The physical examination of a hemodynamically unstable patient is performed coincident with therapy, but care and thoroughness are not precluded by these circumstances. When an obvious intracranial, thoracic, or orthopedic injury is present, abdominal symptoms or findings may be obscured, and abdominal injury must always be considered. Chest trauma itself is a risk factor for coincident intraperitoneal pathology. This is particularly true in cases of possible multiple blunt trauma accompanied by a head injury, coma, or obtunded mental status resulting from drug or alcohol ingestion.

The abdomen, then, should neither be ignored nor be the sole focus of the emergency physician. All of the patient’s clothing must be removed, and a careful inspection of the patient’s body should be conducted, to include the scalp, perineum, skin folds, and beneath the hair. Wounds from penetrating trauma can be exceptionally small, difficult to find, but yet lethal.

Hypotension in the acute stage results from hemorrhage that is most often from a solid visceral or vascular injury. Traumatic pancreatitis may produce significant third-space fluid loss, but hours to days are usually required for this to appear, and shock is an uncommon presentation. When hypotension accompanies significant multiple blunt trauma and is unexplained, one should assume the presence of intraperitoneal hemorrhage until it is excluded. However, a known extra-abdominal source of hemorrhage does not mitigate the need to evaluate the peritoneal cavity. A head injury alone does not explain shock except in cases of profound head injury or in the very small infant for whom traumatic intracranial or extracranial (e.g., cephalohematoma) blood loss may be proportionally substantial.

In cases of penetrating trauma, inspecting the abdomen for entrance and exit wounds may help determine the path of injury. Distention can occur as a result of pneumoperitoneum, gastric dilation, or ileus produced by peritoneal irritation. An ecchymotic discoloration of the flanks (Gray-Turner sign) or umbilicus (Cullen’s sign) indicates retroperitoneal hemorrhage, but these signs are usually delayed for 12 hours to several days. Abdominal contusions can result from various implements, and when caused by lap belts, they herald abdominal injuries in one third of cases.

Markedly decreased or absent bowel sounds have traditionally been considered one of the more reliable clinical parameters of intraperitoneal injuries. However, the presence of audible peristalsis, although uncommon, does not rule out ileus or serious injury, and the absence of bowel sounds occurs in up to 20% of patients with a suspected injury from abdominal trauma who prove to have no such injury at laparotomy. In such instances, coexisting electrolyte disturbances or thoracoabdominal emphysema, but the presence of either is highly correlated with abdominal injuries. The evaluation of rectal tone is an important part of determining the patient’s spinal cord integrity, and palpation of a high-riding prostate suggests urethral injury.

A nasogastric tube should routinely be placed in the absence of severe maxillofacial trauma to decompress the abdomen, decrease the likelihood of aspiration, and determine whether blood is present. Orogastric placement should be used when a cribiform plate fracture or unstable midface fractures are suggested to prevent intracranial insertion. Foley catheters are useful in unstable patients for following renal output and rapidly obtaining urine samples to search for blood, myoglobin, and toxins.

Thus, a number of signs are valuable in assessing the patient with abdominal trauma. Although the presence of physical findings makes intraperitoneal injury more likely, their absence does not preclude serious pathology, and none is exclusively diagnostic of a specific injury. Extensive observation and the use of certain laboratory procedures greatly help prevent erroneous or missed diagnoses.

Penetrating Abdominal Trauma

Stab Wounds. Serial physical examinations performed by the same observer are gaining acceptance in centers where these have been found useful, particularly with patients who are alert, communicative, and neurologically intact. The presence of intoxicants does not necessarily preclude reliance on examination but may undermine its value. In other series, patients with impressive physical findings after penetrating trauma to the abdomen have undergone exploratory laparotomy, with negative results in 14 to 28% of cases. Moreover, up to one third of patients with significant intra-abdominal injuries have no suggestive physical signs, particularly when a retroperitoneal injury has occurred.

Gunshot Wounds. As with blunt or other modes of penetrating trauma, there is dispute regarding the value of the physical examination of patients with abdominal GSWs. In various series, 20% of patients with a documented intraperitoneal injury had no peritoneal signs before exploration. Moreover, objective physical findings suggestive of intra-abdominal damage have been misleading and falsely positive in 15% of patients in whom laparotomy revealed no injury. Other authors contend that selective management can be undertaken safely when physical examination is the fundamental evaluative measure.
Blunt Abdominal Trauma

Overall, the accuracy of the physical examination in patients with BAT is 55 to 65%. The initial presentation may be exceptionally benign in cases of blunt intra-abdominal injury. The most reliable symptoms and signs in alert patients are pain, tenderness, and peritoneal findings, particularly when risk factors for abdominal injury are present. When altered sensorium intercedes, the physical signs become less reliable. Frequent evaluations by the same examiner are indicated even in alert patients but especially in sensorium-altered patients, particularly as they become more lucid.

**DIAGNOSTIC STRATEGIES**

**Laboratory**

Hematologic and chemical values are of limited use in the treatment of the acutely traumatized patient. These laboratory tests should be considered adjuncts to diagnosis and not substitutes for clinical assessment.

**Hematocrit**  
The hematocrit reflects baseline value, extent of and time from hemorrhage, exogenous fluid administration, and endogenous plasma refill. The last of these is a physiologic compensatory shift of extracellular fluid into the intravascular space, the intent of which is to restore the original blood volume. Based on a study of volunteers sustaining a 10 to 20% blood loss, this restoration proceeds at a rate of only 40 to 90 mL/hr for the first 10 hours and requires 30 to 40 hours for completion.

However, patients evidencing hemorrhagic shock with a blood loss of at least 40% demonstrate much faster plasma refill rates, estimated as high as 1500 mL in the first 90 minutes after injury, with significant decreases in hematocrit within this period. Although the hematocrit is an easily acquired measure, it is often a conundrum when viewed in isolation, and serial determinations are more helpful.

**White Blood Cell Count.** The white blood cell (WBC) count has little discriminatory value in cases of abdominal trauma, particularly its acute phase. The WBC count may be normal or may show a modest leukocytosis (12,000–20,000/mm³ with or without left shift), which can occur in the setting of multisystem trauma as a result of stress-induced demargination in the absence of any intra-abdominal process or may result from tissue injury, acute hemorrhage, or peritoneal irritation.

**Chemical**

**Pancreatic Enzymes.** Neither serum amylase nor lipase is useful in the evaluation of acute abdominal trauma. Normal levels do not exclude a major pancreatic injury, and elevated values may be caused by any of an assortment of reasons in addition to an injured pancreas. The use of serum amylase isoenzyme measurements has not appreciably improved accuracy. Nontraumatic causes of hyperamylasemia include several diseases and the use of alcohol, narcotics, and various other drugs. Amylase or lipase may also be elevated with pancreatic ischemia produced by the systemic hypotension that often accompanies trauma. Clearly, these enzymes are neither highly specific nor sensitive for pancreatic injuries. Elevated or rising levels may indicate damage but in themselves are not conclusive. In these cases, clinical correlation and further investigation are indicated.

**Base Deficit.** Metabolic acidosis in the setting of trauma can suggest the presence of hemorrhagic shock. This can be witnessed chemically as a decreased serum bicarbonate level, increased base deficit, or elevated serum lactate level. Although normal values do not exclude abdominal injury, substantive abnormalities, such as a base deficit greater than or equal to 6, may be predictive. These findings should be considered in clinical context, because the resolution of the laboratory findings will lag behind the clinical improvement of the patient.

**Liver Function Tests.** Elevated serum transaminases can result from hepatic trauma but do not distinguish minor contusions from severe injury. Alternatively, these may be symptomatic of alcohol-induced liver damage. Elevated liver transaminase levels may be useful for screening pediatric patients for intentional trauma (see Chapter 63).

**Toxicology Analysis.** Screens for ethanol and drug use are often used in trauma centers. Their utility in the management of abdominal trauma per se has not been established, particularly in patients with normal mental status. Positive study findings may prompt the emergency physician to interdict and the patient to decrease the recidivistic use of ethanol or drugs.

**Radiology**

Resuscitation and initial stabilization measures must always precede abdominal radiographic studies. Basic plain radiography in the trauma bay is of limited value, although a chest film to screen for significant hemo- or pneumothorax before the patient is transferred to the CT scanner facilitates early stabilization of these injuries. Any potential cervical or lower spinal injury must be presumed present based on the mechanism of the trauma, the patient’s symptoms, and physical examination findings. A portable cross-table radiograph in the trauma bay is insufficient to exclude any such injury. In the hemodynamically stable patient, depending on physical findings and whether the patient is able to communicate about pain, pelvis radiographs may be deferred to the radiology suite or omitted entirely (see following section). In patients whose symptoms and signs demonstrate a likely need for exploratory laparotomy, delay to operation because of radiologic diagnostics is permissible only when the patient has been stabilized and only if studies might aid in determining management. Adequate radiographic detail cannot be achieved in an uncooperative patient. Trained personnel must accompany any patient whose condition might deteriorate precipitously. Moving the patient from the relative security of the trauma resuscitation room to the radiology suite creates increased risk for the patient because of the relative decrement in monitoring and personnel in attendance.

**Plain Films**

The chest radiograph and anteroposterior pelvic films can be invaluable in some cases of penetrating and blunt trauma, depending on the presentation and results of initial evaluation. Plain abdominal films can demonstrate the location or track of missile(s) in gunshot and shotgun injury but are of little value in blunt trauma or nonprojectile penetrating trauma, particularly if CT of the abdomen is anticipated. If plain radiography of the abdomen is done, the finding of rib, pelvic, vertebral body, or transverse spinous process fractures in the blunt trauma patient warrants special consideration for nearby visceral damage.

Very small quantities of readily detectable free intraperitoneal air are present in most patients with gastric, duodenal bulb, and colonic perforations but in fewer than one fourth of those with jejunal and ileal perforation. These are seen more readily on CT than plain films. Free intraperitoneal air uncommonly can be generated by mediastinal or pulmonary injury,
as well as by barotrauma, and thus its presence is not pathognomonic of hollow viscus perforation. Intraperitoneal air is mobile, and to maximize visualization the patient should be kept in the appropriate upright or decubitus position for 10 to 15 minutes, if this is tolerable, before upright chest or decubitus abdominal radiographs are obtained. In upright films, air is located under the diaphragm or the central tendon of the diaphragm anteriorly. In supine films, air tracks under peritoneal attachments, such as the falciform ligament and urachus, up to the anterior abdominal wall. On films in which the patient is in a lateral decubitus position, air is located in the superior flank and outlines the lateral liver edge (Fig. 43-1). In cases of gastric perforations, air may be limited to the lesser sac. A rupture of a retroperitoneal hollow viscus can be detected by a stippling pattern outlining the duodenum, kidney, or psoas muscle (Fig. 43-2). Extraperitoneal colonic perforations may extravasate air, which outlines the psoas muscle and perinephric region. All of these injuries are much more readily identified and localized using abdominal CT.

Figure 43-1. Demonstration of free intraperitoneal air on left lateral decubitus film. This is the preferred decubitus position because it avoids confusion with the gastric bubble and splenic flexure.

Figure 43-2. Erect film demonstrates the soap bubble appearance of retroperitoneal air outlining the right kidney. Duodenal perforation is the responsible pathologic condition.

Computed Tomography

Over the last 30 years, CT has continued to advance its place among diagnostics for trauma. Evolution to 16- and 64-slice helical and spiral scanners has improved resolution and greatly decreased the time required for the scan itself.39

Advantages. In most situations, CT has supplanted DPL, because of its higher predictive ability for operative lesions and the fact it is noninvasive. CT can define the injured organ and the extent of the injury. It is most accurate for solid visceral lesions and accurately discerns the presence, source, and approximate quantity of intraperitoneal hemorrhage (Fig. 43-3). It can demonstrate active bleeding from the liver or spleen and can be used to determine whether therapeutic angiographic embolization is indicated.40 CT also evaluates the retroperitoneum (Fig. 43-4), an area not sampled by DPL, as well as the vertebral column and can be readily extended above or below the abdomen to visualize the thorax or pelvis.41 CT also provides definitive evaluation for most possible injuries to the urinary tract, including renal artery injury.42 It can also detect other vascular hemorrhage and obviate the need for angiography in some patients.43 CT is particularly helpful in guiding nonoperative management of solid organ damage.44-46 This includes as-needed follow-up studies of convalescing patients with these injuries. It has also proven effective when incorporated in delayed fashion for patients with decreasing hematocrit, increasing base deficit, or subtle examination changes. By minimizing the incidence of nontherapeutic laparotomies for self-limited injury to the liver or spleen, it decreases morbidity and cost attendant to this operation.47 Increasingly, trauma centers are using CT with intravenous (IV) contrast only, as it has been shown that little additional

Figure 43-3. Grade 4 splenic laceration (arrow).
Disadvantages. Disadvantages of CT include its insensitivity for injury of the pancreas, diaphragm, small bowel, and mesentery, although detection of these injuries is improving. These latter two are particularly worrisome because isolated coincidental hollow viscus injury in patients with blunt trauma, although uncommon, is not rare, and increased morbidity and death can ensue if diagnosis is missed or goes undetected for a prolonged period. Findings on CT scans, including the possible quantity of hemoperitoneum or the presence of isolated free fluid, are not able to forecast well the need for operative intervention. Complications can result from IV contrast administration or uncommonly from contrast material administered orally. Moreover, oral contrast delivery to opacify the bowel is infrequently useful and often omitted. Oral contrast is not necessary in the follow-up evaluations of stable splenic injuries.

Technique. The technique for CT is reasonably standardized, but certain conventions are debated. The studies should begin in the low chest and be taken through the pelvis. If chest scanning is also required, a single continuous scan is obtained from the root of the neck to the floor of the pelvis. “Quick look” but less thorough studies are not effective and should be avoided, and preliminary reads from the CT control room do not have the added accuracy of reconstituted scans and may, therefore, miss subtle injuries such as intimal tears of the thoracic aorta. Most centers perform enhanced (IV contrast) and nonenhanced scans because the latter alone may not demonstrate intraparenchymal hematomas well. Other practitioners believe that the noncontrast portion contributes little other than time to the procedure.

Contrast Studies

Contrast studies with a water-soluble medium (e.g., Gastrografin) can be helpful in cases of suggested gastric, duodenal, and rectal perforations (Fig. 43-6). Barium mixtures should be used to visualize intramural duodenal hematomas. CT may be able to discern duodenal hematomas and can distinguish these from perforations.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is usually impractical and sometimes impossible to perform in the acute phase of multiple blunt trauma. Currently, in acutely injured trauma patients, MRI should be reserved for the evaluation of spinal fractures and elusive diaphragmatic defects.

Angiography

Angiography, a time-consuming procedure, is usually reserved for the unstable patient with blunt trauma and pelvic fracture in whom it can be used to embolize bleeding vessels. It can be a means of staunching solid visceral hemorrhage from blunt trauma, notably of the spleen, and has been used
focused assessment with sonography for trauma (FAST) US examination of Morrison’s pouch, the splenorenal recess, and the pouch of Douglas, which depend on portions of the intraperitoneal cavity where blood is likely to accumulate (Fig. 43-8A–E). Anechoic areas caused by the presence of blood are best visualized when contrasted against solid organs (e.g., liver, spleen, and kidneys). With penetrating mechanisms, an extended FAST (E-FAST) US adding visualization of the pleura can help in the evaluation of the pericardial space and intraperitoneal spaces and detect pneumothorax. US has also been used to inspect thoracoabdominal wound tracts with some success.

Advantages. Ultrasonography carries a host of advantages. It is a portable instrument that can be brought to the bedside in the trauma resuscitation area. Studies of the pericardial, intraperitoneal, and thoracic spaces can be accomplished in less than 5 minutes. FAST US has a sensitivity in detecting as little as 100 mL and, more typically, 500 mL of intraperitoneal fluid that ranges from 60 to 95% in most recent studies, and the specificity for establishing hemoperitoneum is excellent. Therefore, when time is precious in the critical patient, the FAST can provide rapid answers to the key question in the decision matrix, which is whether hemoperitoneum is present. Unlike DPL, the FAST can evaluate intrathoracic structures, is noninvasive, and can be performed serially and by multiple technicians. Unlike CT, it is not a potential radiation hazard and does not require administration of contrast agents. Accuracy correlates with length of training and experience, but expertise can be readily achieved in emergency medicine and surgical training programs. Serially performed FAST increases its diagnostic accuracy for organ injury in patients with BAT. Furthermore, E-FAST adds thoracic windows to detect the presence of pneumothorax in patients presenting after either penetrating or blunt abdominal trauma. These additional views detect pneumothorax with a sensitivity of almost 59% and a specificity of up to 99% compared with CT; but more importantly it is three times more sensitive than a portable supine chest radiograph done in the trauma bay, which has a sensitivity of only 20%. Newer studies advocate adding sono graphic contrast to further delineate solid organ injuries with minimal hemoperitoneum, especially those of the spleen and liver, which might be amenable to nonoperative management. Overall, US can serve as an accurate, rapid, and less expensive diagnostic screening tool than DPL or CT.

Disadvantages. The FAST study does not image solid parenchymal damage, the retroperitoneum, or diaphragmatic defects well. It is technically compromised by the uncooperative, agitated patient, as well as by obesity, substantial bowel gas, and subcutaneous air. Indeterminate studies require follow-up attempts or alternative diagnostic tests. It is less sensitive and more operator-dependent than DPL in revealing hemoperitoneum and cannot distinguish blood from ascites. For unclear reasons, US has a high (31%) false-negative rate in detecting hemoperitoneum in the presence of pelvic fracture. The FAST study, as well as DPL, does not detect the presence of solid parenchymal damage if free intraperitoneal blood is absent, as in subcapsular splenic injury. Finally, US is poor at recognizing bowel injury in which hemorrhage tends to be inconsequential, and failure to diagnose hollow viscus perforation in a timely manner can have catastrophic results.

Diagnostic Peritoneal Lavage

Although largely supplanted by the FAST examination and CT, DPL still has a role in certain cases. DPL comprises two interrelated steps. The first is the attempted aspiration of free peritoneal blood. The recovery of
10 or more milliliters of frank blood from the peritoneum is a strong predictor of intraperitoneal injury, and the procedure is then terminated. If aspiration findings are negative, lavage is conducted in which the peritoneal cavity is washed with saline. This fluid is introduced by catheter, recovered by gravity drainage, and analyzed. The sole absolute contraindication to DPL is the established need for laparotomy. Relative contraindications include prior abdominal surgery or infections, coagulopathy, obesity, and second- or third-trimester pregnancy.

The lavage catheter may be introduced into the peritoneal space by a closed method in which the catheter is inserted in a blind percutaneous fashion by the Seldinger technique; a semiopen technique in which sharp and blunt dissection to the rectus fascia is followed by Seldinger-based delivery of the catheter; and an open technique, which extends the semiopen method through the rectus fascia with direct visualization of the peritoneum (Table 43-1).74

**Advantages.** In cases of blunt trauma, DPL’s primary remaining use is the triage of the patient who is hemodynamically unstable and has multiple injuries with an equivocal FAST examination. In this complex scenario, DPL can promptly reveal or exclude the presence of intraperitoneal hemorrhage and can serve as an indication for laparotomy. Rarely, DPL is used to discern potentially serious bowel perforations in patients who are poor candidates for serial clinical observations (e.g., those with coma) and for whom other diagnostic methods can be unreliable.75

After a stab wound to the abdomen, low chest, flank, or back, DPL can meet three needs: (1) immediate disclosure...
of hemoperitoneum, particularly in a patient who may have mediastinal or pulmonary causes of or contributors to hypotension, (2) determination of intraperitoneal organ injury, and (3) detection of isolated diaphragmatic violation. Laparotomy is undertaken more commonly on clinical grounds for GSWs. In these situations, DPL can serve these same tasks, but it is used far less often.76

**Disadvantages.** The morbidity associated with DPL occurs at a low rate and can be categorized as local or systemic infection, intraperitoneal injury, and technical failure. Wound complications, including hemoma and infection, occurred in 0.3% of cases in two large reviews.77

Technical failure can result in an inaccurate study and difficulty with fluid collection. A faulty technique with inadequate hemostasis or the insertion of the catheter through an abdominal wall hemoma can create a hemoperitoneum of sufficient magnitude to produce positive results. In addition, DPL is exquisitely sensitive for hemoperitoneum and in a hemodynamically stable patient can lead to unnecessary laparotomy. False-negative interpretations can result from the failure to recover lavage fluid. This can occur in the following circumstances78: (1) inadvertent placement of the catheter into the preperitoneal space, (2) compartmentalization of fluid by adhesions, (3) impedance of fluid egress by obstructing omentum, and (4) large diaphragmatic tears typical of blunt mechanism that permit lavage fluid to move from the intra-abdominal or retroperitoneal space into the peritoneal cavity.

**Results.** A battery of hematologic, chemical, enzymatic, and microscopic tests has been applied to peritoneal aspirate and lavage effluent. Gross inspection of the effluent alone is considered neither adequate nor reliable. There is little correlation between fluid color and cell count.

In cases of blunt trauma, the aspiration of 10 mL or more of blood has a positive predictive value of greater than 90% for intraperitoneal injury, predictably solid visceral or vascular, and is responsible for approximately 80% of true positive DPL findings in blunt trauma.77 The red blood cell (RBC) count of the lavage fluid is the next most widely used and accurate parameter (Table 43-2).

In cases of blunt trauma, an RBC count exceeding 100,000/mm³ carries a sensitivity exceeding 90% (see Table 43-2).81 The incidence of visceral injury with counts less than 100,000/mm³ ranges from 1 to 29%. It is recommended that patients with equivocal RBC counts be carefully observed for 12 to 24 hours.82 Most injuries associated with RBC counts less than 100,000/mm³ are to hollow viscera, and clinical manifestations of these should develop within this observation period. Some advocate lowering the threshold to 10,000 RBC/mm³ to decrease missed hollow viscus injury.83 However, others cite an increased negative laparotomy rate with the lowered threshold and instead advocate adding a WBC count above 500/mm³ or the presence of bile or amylase to the 100,000/mm³ cutoff to better diagnose these injuries.84

With anterior abdominal stab wounds, aspiration of 10 mL of gross blood or the return of lavage fluid with an RBC count greater than 100,000/mm³ carries a sensitivity exceeding 90% (see Table 43-2).81 The incidence of visceral injury with counts less than 100,000/mm³ ranges from 1 to 29%. It is recommended that patients with equivocal RBC counts be carefully observed for 12 to 24 hours.82 Most injuries associated with RBC counts less than 100,000/mm³ are to hollow viscera, and clinical manifestations of these should develop within this observation period. Some advocate lowering the threshold to 10,000 RBC/mm³ to decrease missed hollow viscus injury.83 However, others cite an increased negative laparotomy rate with the lowered threshold and instead advocate adding a WBC count above 500/mm³ or the presence of bile or amylase to the 100,000/mm³ cutoff to better diagnose these injuries.84

With lower chest stab wounds, a positive RBC count of 5000 to 10,000/mm³ should be considered as evidence of diaphragmatic injury. Because of the more serious nature and greater likelihood of an injury with abdominal gunshot wounds, RBC counts of 5000/mm³ are advocated as the cutoff, because these signal peritoneal penetration, if not injury.77 Increasingly, laparoscopy has supplanted DPL for the purpose of identifying or excluding diaphragmatic injury in lower chest penetrating trauma.

WBCs enter the peritoneal cavity as part of shed blood or in response to an inflammatory stimulus. However, this finding lags after injury by 3 to 6 hours. Initial elevated counts greater than 500/mm³ are nonspecific and unhelpful.85 At no time after injury can an isolated elevated WBC count be considered to accurately indicate significant intra-abdominal injury, and its use, therefore, is not recommended.

Although used in the past, elevations in lavage amylase and the presence of bile are nonspecific.

Other parameters, such as Gram’s stain of lavage fluid, are not of diagnostic value.

**Local Wound Exploration**

Because stab wounds do not reach the peritoneum in a significant number of cases, local wound exploration (LWE) is useful in determining the depth of penetration. The wound should
be infiltrated with a local anesthetic containing epinephrine and thoroughly prepared for exploration. The stab wound may be extended if required and then carefully visualized through each successive layer of tissue. Blind probing with digits, instruments, or cotton-tipped swabs is inaccurate, unless the peritoneal cavity is obviously freely entered. Blind probing of chest injuries adds no potential additional information and may be hazardous. If LWE indicates that the peritoneum is violated, further diagnostics are indicated. Likewise, when the end of the wound tract cannot be determined clearly, peritoneal entry must be presumed. When the stab wound is documented to be superficial to the abdominal cavity, the patient can be safely discharged home after appropriate wound care.

LWE is generally advocated in cases of anterior abdominal stab wounds, but in other areas the decision is less clear. Abdominal, flank, and back wounds have been evaluated with this method, particularly when the entry is more superficial. The flesh of obese or heavily muscled patients in particular can present technical problems and decrease the reliability of exploration while increasing its risk. Wound explorations in patients with multiple entrances are not economically justifiable, and peritoneal penetration should be assumed. Deep exploration over the thoracic cage is precluded by attendant complications to neurovascular structures and pleura. However, careful inspection of superficial chest wounds (e.g., slash wound) is safe and can provide valuable data. CT, laparoscopy, or thoracoscopy is occasionally used in lieu of LWE.

Special Procedures

Laparoscopy

Laparoscopy is increasingly finding a role in some trauma centers. General anesthesia in an operating suite is required. Laparoscopy has been most useful in assessing penetrating trauma, especially for injury to the diaphragm and intrathoracic abdominal organs. It has a reported sensitivity of 87.5% and specificity of 100% for detection of diaphragmatic injury after PAT, with a positive predictive value of 100% and negative predictive value of almost 97%. Organs repaired via the laparoscope include the diaphragm, solid intraperitoneal viscera, stomach, and small bowel. Wound tracts have been assessed as accurately as by LWE. Very little experience in blunt trauma has been documented thus far.

Drawbacks of laparoscopy include poor sensitivity for hollow visceral injury, notably to the small bowel, and difficulty in assessing the retroperitoneum and extent of damage to the liver and spleen. Complications can result from trocar misplacement. If the diaphragm has been violated by the original trauma, pneumothorax or tension pneumothorax can occur during the insufflation phase. At this time, the greatest value of laparoscopy is in the evaluation and management of equivocal penetrating wounds to the thoracoabdominal region in stable patients. This approach can realize a reduced incidence of nontherapeutic laparotomy.

DIFFERENTIAL CONSIDERATIONS

Trauma versus Medical Condition

Medical and traumatic pathologic conditions can be coincident or lead one to the other. For instance, hypoglycemia or a generalized convulsive seizure may precipitate a motor vehicle crash, and the patient’s altered mental status may incorrectly be ascribed to closed-head injury, delaying diagnosis of the medical condition. Patients with infectious mononucleosis can experience splenic rupture after relatively trivial trauma, and presentation may be delayed. Finally, patients who have pre-morbid coagulopathy or who are on therapeutic anticoagulation may sustain serious intracranial hemorrhage from otherwise unconcerting head trauma.

Single versus Multisystem Trauma

Emergency physicians must be wary and not miss the proverbial forest for the trees. For instance, the pedestrian struck by a car who has an alleged isolated tibiofibular fracture may well harbor significant intra-abdominal pathology as well, irrespective of a nontender abdomen.

Single versus Multiple Intraperitoneal Organ Injury

There has been an increasing trend toward nonoperative management of known intraperitoneal solid organ injury, specifically of the spleen and liver. It must be remembered, however, that coincident hollow viscus pathologic lesions may exist but not be discernible initially to clinical examination or certain diagnostic studies.

Intraperitoneal Injury versus Necessary Laparotomy

Formerly, suspicion or knowledge of any intraperitoneal injury mandated laparotomy. Now, diagnostic effort is appropriately aimed at determining whether surgery is necessary or whether the injury is self-limited and does not require repair measures.

MANAGEMENT

General Measures

Field Treatment

The field approach to multiple or serious trauma focuses on rapid transportation to a capable receiving ED. The initial measures taken vary with the need for active airway management, the presence of concomitant injuries, and the skills of the first responder personnel. Hemorrhage is the major life threat in cases of PAT or BAT, and two large-bore IV lines should be inserted in transit when possible. Penetrating wounds and eviscerations in particular should be covered with sterile dressings. Contact should be made with the base-station physician to communicate pertinent matters of the history, vital signs, treatment measures and their effects, and the estimated time of arrival.

Emergency Department

The general principles of trauma care apply (see Chapter 33). The use of diagnostic aids for abdominal trauma should be carefully restricted according to the patient’s stability and the usefulness of the information sought in guiding management. Those patients who do not require immediate laparotomy will likely undergo one or more diagnostic procedures to determine whether abdominal injury exists and, if so, whether operative intervention is necessary.

Thoracotomy. Thoracotomy and subsequent cross-clamping of the descending aorta have been used to stabilize patients with thoracoabdominal injuries and profound hypovolemic shock. However, it is rarely lifesaving in the ED (see Chapter 33).

In a patient with massive abdominal injuries and hypotension secondary to a hemoperitoneum, the primary purpose of
aortic cross-clamping is to shunt available blood into the coronary and cerebral circulation during resuscitation. Second, it is helpful in providing proximal bleeding control of certain vascular and parenchymal injuries, although continued bleeding can occur via collateral flow, until direct clamping, packing, or repair is achieved. Third, it can allow direct atrial access for rapid fluid administration. Finally, it has been advocated as a prophylactic measure in the operating room before laparotomy is performed for a massive hemoperitoneum. In certain instances, abdominal decompression, particularly in the face of a vascular injury, may result in worsening shock and death.

Antibiotics. An intestinal perforation and spillage can occur after blunt or, more commonly, penetrating trauma to the abdomen. Anaerobes and coliforms are the predominant organisms found. Antibiotics given prophylactically have been demonstrated to be effective in decreasing the incidence of intra-abdominal sepsis and should be given as soon as such an injury is suggested. A single preoperative dose of a broad-spectrum antibiotic or combination of antibiotics that covers both aerobic and anaerobic organisms, such as piperacillin-tazobactam (3.375 mg IV), is recommended.90,91

Penetrating Abdominal Trauma: Stab Wounds

Diagnostic Studies

The purpose of diagnostic studies is to determine whether the peritoneal cavity has been violated or whether there is intraabdominal injury requiring operative repair. Tests used for the former purpose include plain films, LWE, US, and laparoscopy. Those most commonly used with the latter intent are DPL, serial physical examinations, laparoscopy, US, and CT. These modalities are undertaken only if clinical determinants that would mandate laparotomy do not exist.

Management

Selective management of abdominal stab wounds is now well accepted because of the relatively low incidence of intraperitoneal injuries coupled with the success of various diagnostic strategies.92 The appropriateness of these strategies is predicated on the basis of penetration site, clinical status of the patient, and the experience and preference of an institution and its personnel. Formerly, the goal of mandatory exploration of all stab wounds was to eliminate missed injuries. Currently, selective management has resulted in a tremendous reduction in unnecessary laparotomies and their associated morbidity, with minimal and acceptable loss in sensitivity for significant intraperitoneal injury. Although certain authors promote the relative safety of nontherapeutic operations, others cite considerable immediate and delayed hazards, as well as increased cost.9 It is generally preferred that the nondiagnostic laparotomy rate be less than 15%.

Anterior Abdomen. In approaching the management of stab wounds to the anterior abdomen, the clinician is faced with three fundamental tasks. The first and most important is to determine whether clinical indications point to the need for laparotomy. The presence of one or more of these indications, particularly in the context of an unstable patient, sets the course to exigent operation. If none is found, however, the clinician may address the second issue of whether the peritoneal cavity has been violated. If it can be definitively demonstrated that it has not, no further diagnostics are required, and the patient can be discharged. If the cavity has been violated, or if it cannot be determined that the cavity has not been violated, the third question must be answered: Is there an injury and, if so, is laparotomy required? Figure 43-9 is an algorithm based on the answers to these three questions and follows clinical indicators of injury, LWE, DPL, CT, and other radiologic modalities. Other strategies rely more heavily on other techniques, such as serial abdominal examinations or laparoscopy.83,92-96

Step 1: Clinical Indications for Laparotomy. Seven clinical determinants are used to predict the need for laparotomy after stab wounds to the abdomen (Table 43-3). Although there is consensus regarding the reliability of some of these, each has suboptimal predictive value.

1. Hemodynamic compromise. This is the preeminent indication of the need for laparotomy and is the most frequent reason that a patient is taken urgently to the operating room without preliminary diagnostic studies. This is typically an appropriate approach after middle and lower abdominal penetration.15,95,97,98 However, stab wounds to the upper abdomen and lower chest may produce hemodynamic instability because of intrathoracic hemorrhage, pneumothorax, or pericardial tamponade.

2. Peritoneal signs. There is considerable debate over the reliability of peritoneal signs, particularly in the early postinjury period. Among physical examination findings, unequivocal peritoneal signs have the highest positive predictive value, whereas an entirely normal examination even in the presence of mild to moderate intoxication has the greatest negative predictive value for therapeutic laparotomy.15,95,97

Figure 43-9. Anterior abdomen stab wound algorithm. *Plain films, focused assessment with sonography for trauma (FAST), laparoscopy (LPY), and computed tomography (CT) can also assess peritoneal entry. †CT, diagnostic peritoneal lavage (DPL), serial physical examinations (SPEs), or LPY can be used in singular or complementary fashion depending on the clinical scenario. ‡Expectant management of injuries is infrequently attempted. FAST, focused assessment with sonography for trauma; LAP, laparotomy; LWE, local wound exploration.

3. **Evisceration.** With isolated omental evisceration, both a selective and a mandatory operating approach have been espoused. Omentum has been successfully ligated, excised, and restored to the peritoneal cavity. However, patients with viscus or omental evisceration sustain up to an 80% incidence of major intraperitoneal injury, rendering laparotomy a reasonable next step in management.

4. **Left-sided diaphragmatic injury.** In contradistinction to blunt mechanism, penetrating trauma to the diaphragm produces small tears and evanescent clinical clues to their presence. Thus, clinical examination and plain chest films are rarely diagnostic of injury. Other diagnostic measures, such as DPL or laparoscopy, or a mandatory laparotomy approach is necessary to discern this pathologic condition.

5. **Gastrointestinal hemorrhage.** Recovery of blood via a nasogastric tube or emesis may reflect a violation of the stomach or duodenum but is an unusual occurrence. Likewise, examination of the rectum or vagina may reveal hemorrhage that is the result of intraperitoneal or retroperitoneal trauma.

6. **Implants in situ.** The conservative and widely held maxim is to remove implants in situ of the torso in the operating room. This is to ensure expeditious control of hemorrhage should the implant reside within a vascular space or highly vascularized organ. Although implants in situ are most safely removed in the operating room, exceptions to this practice exist. These include situations in which ED resuscitation is impeded by the presence of the implant or the patient is at high risk for significant morbidity from nontherapeutic laparotomy because of severe comorbid conditions or pregnancy, for example.

7. **Intraperitoneal air.** The presence of free intraperitoneal air is often not sought because of the insensitivity and non-specificity of this finding. Free intraperitoneal air can impute communication of the weapon with the intraperitoneal space or the presence of pulmonary or mediastinal injury. Thus, it does not necessarily indicate hollow visceral perforation and should not be used in isolation as an indicator for operation.

**Step II: Peritoneal Violation.** If clinical indications for laparotomy are absent, a logical next step is assessing the wound tract itself. The presence of peritoneal violation can be determined by a variety of means. There is great value in establishing that a wound tract is superficial to the peritoneal, retroperitoneal, intrathoracic, and pericardial cavities. In this event, the patient can be discharged from the ED after receiving appropriate wound care. If a study is inconclusive, it should be assumed that one or more of these cavities have been violated and that other means of assessment are required. The five methods of assessing the intactness of the peritoneum are as follows:

1. **Evisceration.** Evisceration of bowel or omentum is clear evidence of peritoneal entry. These situations are usually handled by mandatory laparotomy. In certain centers, however, these eviscerations are reduced in the ED and further diagnostics pursued.

2. **Intraperitoneal air.** A finding of intraperitoneal free air on an upright chest or a lateral decubitus abdominal radiograph generally establishes that the weapon has entered the peritoneal cavity and drawn air in with it, has disrupted a hollow viscus, or both. Rarely, a false-positive determination of peritoneal entry can be made when the actual source of intraperitoneal free air is the pulmonary tract.

3. **Local wound exploration.** This has been demonstrated to be an effective tool in determining the depth of the stab wound tract.

4. **Ultrasonography.** US demonstrating hemoperitoneum, pneumoperitoneum, or pericardial effusion identifies peritoneal penetration. However, its reliability as a sole indicator for injury is not as dependable as that in BAT and carries a 15% negative laparotomy rate when used as such. In addition, a negative FAST does not rule out peritoneal violation. US may also be used as an adjuvant to LWE to determine intactness of fascia. Although a small study demonstrated it can positively rule in fascial penetration, it is unreliable to rule this out. Experience with US for this purpose has been successful but very limited.

5. **Laparoscopy.** This has compared favorably with LWE in assessing the wound tract but requires far more expertise and carries a far greater risk of complications. It is the most invasive and costly means of evaluating the integrity of the peritoneum. However, laparoscopy may also discover and serve as the mode of repair of certain diaphragmatic or organ injuries, or both. And some postulate that its use in experienced centers actually decreases length of stay and therefore cost.

**Step III: Injury Requiring Laparotomy.** In this algorithm, patients requiring an operation on clinical grounds have proceeded to laparotomy, and those in whom peritoneal, retroperitoneal, intrathoracic, and pericardial cavity violations have been excluded are discharged home. The patients remaining have presumed or known peritoneal violation. The next consideration is whether injury exists that dictates operative repair, as organ injury is present in just over 60% of patients with peritoneal violation. In any case, patients who reach this stage of evaluation should be observed for at least 12 to 24 hours.

For the past 25 years, the diagnostic standard for addressing the issue of intraperitoneal injury has been DPL. It is especially valuable as a rapid means of determining hemoperitoneum in the critical patient and for the discovery of occult hollow viscus perforation and isolated diaphragmatic injury.
PART II
Trauma / Section Two • System Injuries

However, it is invasive, and thus many centers advocate other less invasive adjuvant testing methods coupled with serial physical examinations as the next step in management, reserving DPL use for those with unreliable exams or wounds in the thoracoabdominal area where diaphragmatic injury must be ruled out.92,95

US may be somewhat less accurate than DPL in establishing the presence or absence of hemoperitoneum, but it can simultaneously ascertain hemopericardium (Fig. 43-10), and in most centers US can be accomplished as quickly as or more quickly than peritoneal aspiration. Emphasis on serial examinations with selective use of other studies on an as-needed basis can be successful when an adequate number of experienced clinicians are available.57,99,101

CT has been particularly useful for potential colorectal trauma or further assessment of patients submitted to serial examination alone. However, some centers routinely perform CT in these cases and not simply for possible colorectal trauma.102,103 Most utilize triple contrast (oral, rectal, and IV), although some newer studies cite equal accuracy with IV contrast only.104 Hollow viscus and occult diaphragmatic injuries remain the most missed injuries on CT (even with use of triple contrast), although with the advent of multidetector CT scanners this is decreasing.105

Laparoscopy works best in experienced hands for restricted indications. However, its routine use is gaining favor in some institutions experienced with its use. Benefits include the ability to detect organ injury (including diaphragmatic injury) and simultaneously repair some injuries, thus decreasing negative and nontherapeutic laparotomy rates.14,99,89,100

Thoracoabdominal. Even a single stab wound to the low chest can violate the mediastinum, thoracic cavity, diaphragm, peritoneal cavity, and retroperitoneum. The risk of diaphragmatic penetration from a left thoracoabdominal stab wound has been measured at 17%.96 When all thoracoabdominal wounds are considered, the risk of occult injury is 7%.100 US can be extremely useful in quickly assessing for hemopericardium and hemoperitoneum in the marginally stable patient when thoracotomy or laparotomy is not already clinically indicated.106 LWE of slash-type wounds may obviate the need for further evaluation. However, the depth of investigation cannot be taken beyond the anterior rib margin to maximize safety and accuracy. Further assessment for intraperitoneal and diaphragmatic injury can be made by DPL. The RBC criterion is lowered to 5000 to 10,000/mm² to optimize sensitivity for isolated diaphragmatic injury.77 Laparoscopy or thoracoscopy can visualize and potentially repair the diaphragm and other organs. Newer multidetector CT and MRI show promise in excluding diaphragmatic injury. CT has a sensitivity of 94% and specificity of almost 96% for detecting diaphragmatic injury. However, equivocal scans must be followed up with more definitive management, including DPL or exploratory laparotomy.105 A very conservative approach to the left lower chest stab wound, in particular, is mandatory exploration. This approach avoids any opportunity for missed diaphragmatic rents and their delayed consequences but results in an exceptionally high incidence of nontherapeutic operation. Rapid-slice helical CT or MRI may provide a solution to this vexing concern, but data are limited to date.

Flank and Back. The incidence of retroperitoneal injuries after stab wounds to the flank and back is greater than with injury to the anterior wall. However, risk of intraperitoneal organ injury is significant, ranging from 15 to 40%.16 Again, LWE can be a useful diagnostic first step. However, the paraspinal muscles are quite thick, rendering the procedure more difficult. DPL is useful for diaphragmatic and intraperitoneal evaluation and, if it yields negative findings, can be followed by CT.18 Triple-contrast CT is becoming the preferred method of evaluation in hemodynamically stable patients, and coupled with observation it may safely allow nonoperative treatment in these patients.89,92

Implant in Situ. It is routinely advised that foreign bodies in situ of the torso be removed under operating conditions. This is considered safest in the event that the implant is intravascular or in a highly vascularized organ. Plain films are generally all that is required. CT may be indicated in stable patients if plain films suggest impalement of major vascular structures. Angiography may also be necessary. For pregnant patients or those with severe comorbid illness in whom unnecessary laparotomy should be strictly avoided, CT may be able to discern the depth of entry and extent of injury. In these cases, the foreign body may be removed safely outside of the operating room.

Penetrating Abdominal Trauma: Gunshot Wounds
Diagnostic Studies
Diagnostic studies are used in a fashion similar to that for stab wounds. Moreover, the same diagnostic agents are applied, although in more restricted circumstances. The principal uses of diagnostic studies are to determine whether the missile has entered the peritoneal cavity or if injury requiring operative intervention has occurred.

Management
Like stab wounds, GSWs typically produce multiple organ injuries and a high incidence of hollow visceral injury. However, the risk of mortality is significantly greater, especially if vascular structures are involved. Missiles striking the low chest commonly penetrate both intrathoracic and abdominal structures, including the diaphragm.

Abdominal GSWs enter the peritoneal cavity in approximately 80% of cases, and in more than 90% of those involving penetration there is intraperitoneal damage.32 These statistics significantly exceed the figures for stab wounds, and most trauma surgeons adjust their management to a conservative bent accordingly. We promote the principle that although selective management is widely accepted for stab wounds, its application in the management of GSWs is more limited, and therefore conservative clinical criteria for mandatory laparot-

Abdominal Gunshot Wound Algorithm

1. **Missile path.** Clear entrance and exit wounds allow for a reasonably reliable estimate of the missile path. However, multiple GSWs ricochet, and the tendency of low-velocity missiles to follow fascial planes of lower resistance can render this approach misleading.

2. **Plain films.** An anteroposterior and lateral projection of the abdomen can assist in placing the missile in the peritoneal cavity, but such estimations are imprecise and are largely unhelpful in patients with through-and-through or multiple GSWs.

3. **Local wound exploration.** Because GSWs produce considerably more tissue damage than stab wounds, LWE is a less useful tool for GSWs of the abdomen, flank, and back. Its role should likely be restricted to low-velocity projectiles with suggested superficial entry. Because of the much greater technical difficulty and hazard in visualizing these extensive missile tracts, there is a tendency to underestimate the degree of damage.

4. **Ultrasonography.** The experience with US in coincidentally assessing wound tracts and the mediastinum for low chest and upper abdominal penetration has been successful but very limited.

5. **Laparoscopy.** Laparoscopy is the most invasive and costly means of evaluating the integrity of the peritoneum. However, it may also discover and serve as the mode for repair of certain diaphragmatic or organ injuries, or both.

6. **CT.** CT has been helpful when bullet trajectory is indeterminate and has shown a sensitivity and specificity of 90.5 and 96%, respectively, for identifying intra-abdominal injury.

**Step III: Injury Requiring Laparotomy.** In most institutions, the algorithm terminates after the second step, in which determination or strong suspicion of peritoneal violation presupposes the need for laparotomy. At more liberal centers, these facts are deemed insufficient and additional diagnostics are undertaken.

1. **Serial examinations.** Patients with normal examination findings or localized wound tenderness can be observed only if clinical circumstances and institutional policy allow. Physical examination may be more reliable than previously thought in the presence of alcohol or illicit drug intoxication.

2. **Diagnostic peritoneal lavage.** Peritoneal lavage has been highly successful in determining or excluding intraperitoneal injury. When DPL is used, all criteria for positivity remain the same with the exception of the RBC count, which is lowered to 5000 to 10,000 RBCs/mm³ to maximize sensitivity.

3. **CT.** Higher resolution scanners may augment the ability of CT to identify hollow visceral damage in addition to solid organ and vascular pathologic lesions.

4. **Laparoscopy.** The greatest use for laparoscopy is in the evaluation of the diaphragm in patients with left thoracoabdominal GSWs who do not have indications for standard operative intervention.

**Thoracoabdominal.** Patients with GSWs to the lowest chest have intraperitoneal injuries reported in 45% of cases. Clinical indications for laparotomy are unchanged. Diagnostic peritoneal lavage is particularly helpful in these cases to discern diaphragm injury, and the RBC threshold of 5000 to 10,000/mm³ produces excellent sensitivity, but a combination of CT and serial examinations is more commonly used.

**Flank and Back.** In the past, operative exploration was generally recommended because of the increased likelihood of a serious injury and the greater fallibility of both the physical examination and DPL in cases of retroperitoneal injuries. However, as
multidetector CT scanners have evolved, contrast CT to delineate retroperitoneal pathologic lesions is typically the initial diagnostic test of choice in a stable patient. As with stab wounds, laparoscopy or observation alone can be attempted in selected circumstances.

**Shotgun Wounds.** Type I injuries can be effectively managed by reserving laparotomy for patients with clear peritoneal signs or progressive abdominal tenderness. Certain authors advocate an expectant approach to type II injuries, stating that small punctures of the bowel cause no wound evisceration and no peritoneal leakage and will spontaneously close. A more prudent approach is to perform laparotomy in cases of these penetrating wounds, especially if there are signs of peritonitis. Reconstruction of abdominal wall defects may be required. Type III injuries are commonly associated with multiple organ injuries, shock, and pronounced tissue destruction, requiring hemostasis and extensive débridement.

## Blunt Abdominal Trauma

### Diagnostic Studies

Most centers assimilate physical examination, bedside ultrasonography, CT, and, less commonly, DPL into a clinical algorithm. Other tests, such as angiography, may be indicated. To reiterate, a clinical assessment of an alert patient that depends on abdominal findings alone is reasonably accurate but is accompanied by both false-positive and false-negative errors. Such an assessment is more hazardous for a patient who is under the influence of a variety of toxins or whose examination is compromised by a head injury, spinal injury, or difficulty in communication resulting from retardation, a language barrier, or age.

The purpose of diagnostic studies in patients with BAT is to discern or eliminate the presence of hemoperitoneum in the patient whose condition is critical and unstable to properly sequence management, and in less urgent circumstances, to demonstrate organ injury that requires operative repair.

**Determining Hemoperitoneum**

**FAST Ultrasonography.** FAST US has a safety advantage in that it can be performed rapidly and conducted in the resuscitation suite in the ED. In contradistinction to DPL, the FAST US is hazard-free, and serial examinations can be undertaken with ease in any patient. In hypotensive patients, the FAST US has excellent sensitivity for hemoperitoneum requiring surgical intervention, and most centers proceed to exploratory laparotomy in these patients. However, in those with a negative FAST, intra-abdominal injury requiring operative repair cannot be excluded.

**Diagnostic Peritoneal Lavage.** DPL is exceptionally sensitive in discovering hemoperitoneum, with a false-negative rate of less than 2%. This procedure can be performed in virtually any patient by varying the site and technical method. Aspiration of the peritoneum generally requires less than 5 minutes.

**Computed Tomography.** Although CT can both visualize and estimate the quantity of hemoperitoneum, the time required to accomplish the procedure, including transport of the patient and setup, can be problematic, depending in part on the location of the scanner. Moreover, the ability to carry out CT in a safe manner depends on the availability and expertise of personnel to monitor the patient while he or she is in the CT scanner.

**Demonstrating Organ Injury That Requires Laparotomy.** Indications for the respective studies vary with clinical need and with the experience, resources, and attitudes of individual institutions.

**Ultrasonography and Diagnostic Peritoneal Lavage.** Prompt FAST US (or, less commonly DPL) is clearly warranted in the acutely injured and unstable patient with multiple trauma.

The primary value of the FAST US is in the search for hemoperitoneum. It is far less reliable in specifying organ pathology, with the exception of traumatic pancreatic pseudocysts.

**Computed Tomography.** CT alone is sufficient and appropriate in the patient who is hemodynamically stable and has no obfuscating clinical factors. The great advantage of CT is its ability to identify specific organ injuries and simultaneously evaluate the retroperitoneum. It is the most capable instrument in diagnosing liver and spleen pathologic lesions, and it allows visualization and semiquantitation of hemoperitoneum.

**Laparoscopy.** At this time, the role of laparoscopy in trauma cases is relegated mostly to a penetrating mechanism.

**Complementary to CT if HVI suspected.

††SPEs are unreliable in the patient with CHI.

‡‡May be more appropriate if helical CT is primary study for BAD or can be rapidly acquired.

BAI, blunt aortic injury; CHI, closed head injury; CT, computed tomography; DPA, diagnostic peritoneal aspiration; DPL, diagnostic peritoneal lavage; FAST, Focused Assessment with Sonography for Trauma; HVI, hollow viscus injury; IPH, intraperitoneal hemorrhage; OI, organ injury; SPEs, serial physical examinations.
Chapter 43 / Abdominal Trauma

Management

In cases of blunt trauma, it is the exception when a patient undergoes laparotomy based on clinical grounds alone. Far more typically, one or a complementary battery of diagnostic tests are performed. The choice of these tests is influenced by the patient’s hemodynamic status, the clinical scenario, and the institution’s resources and preferences (Fig. 43-12).

Clinical Indications for Laparotomy. Immediate laparotomy after injury from a blunt mechanism is rarely determined solely by clinical parameters. Potential indications are any of the following (Table 43-5):

1. Unexplained signs of blood loss or hypotension in a patient who cannot be stabilized and in whom intra-abdominal injury is very strongly suggested
2. Clear and persistent signs of peritoneal irritation
3. Radiologic evidence of pneumoperitoneum consistent with a viscus rupture
4. Evidence of a diaphragmatic rupture
5. Persistent, significant gastrointestinal bleeding seen in the nasogastric return or in vomitus

Establishing the need for urgent celiotomy on clinical grounds is particularly problematic in the patient with multiple blunt injuries. Numerous extra-abdominal potential sources of hypotension exist. In addition, there is often coincident head injury or intoxication to further impair the reliability of examination. A nontherapeutic laparotomy may imperil the patient, not so much because of the potential morbidity of the procedure but rather because more vital diagnostic and therapeutic steps are delayed. Where confusion exists, corroborative diagnostic tests are strongly preferred.

Hemodynamically Unstable Patients. In the patient with multiple blunt injuries who is threatened by shock, three cavities are immediately targeted. Chest and pelvic radiographs are performed to identify the source of blood loss in the thoracic and retroperitoneal spaces, respectively. FAST US or peritoneal aspiration is undertaken to reveal or exclude the presence of blood in the peritoneal cavity. Hemoperitoneum in a clinically unstable patient is a mandate for laparotomy.
